The Recognition of Subsidiary Factors in the Ætiology of Infective Diseases

PRESIDENT'S ADDRESS

By REGINALD LOVELL, D.Sc., Ph.D., M.R.C.V.S.

INTRODUCTION

ÆTIOLOGY means that part of any special science which deals with causes, and the investigation of infective diseases includes the study of more than one factor. Consideration must be given not to the infective agent alone but also to the relative importance of general hygiene, nutrition, habits, species of animal, breed, sex, age and environmental conditions. Infective diseases apparently never die out and Greenwood *et al.* (1936) wrote of their work on experimental epidemiology in mice: "The disease will never die out. Since in experimental practice a herd may be reduced to a very small number of individuals, it might happen that the disease became extinct. But we think our experience is wide enough to demonstrate that such an event would be a mere accident of small numbers, and that in large herds maintained under the conditions of our study the disease will be perennial." Some mice existed in a state of infection-equilibrium and many immunized survivors were infected and apparently infective for normal mice. This immunization may have been engendered by natural sublethal or latent infection and this is an essential factor in the immunization of any human or animal herd. Although we recognize "epidemic strains" of bacteria which, when introduced into a herd or community exact their toll, it is equally important for us to consider latent infection and those factors which may influence the epidemic characteristics of a strain and are therefore concerned in the ætiology of infective diseases. The following aspects have some bearing on the problem :

(A) The bacterial flora of normal healthy human beings and animals and the mechanism whereby the potential pathogens assume an infective role.

(B) The resistance of individuals as far as we are able to judge by examination of body fluids for antibodies and bactericidal substances.

(C) The different environmental and subsidiary factors which initiate infective diseases and break down any natural immunity.

(A) *The bacterial flora of normal healthy individuals.*—

We are mainly concerned with the potential pathogens harboured by man and animals. During the years 1930–1937, an extensive study of the nasopharyngeal bacterial flora of different groups of persons in London and S.E. England was made by Straker, Hill and Lovell (1939); this was an extension of one made in Manchester a few years earlier (Report, 1930). On the basis of these studies we find that a single examination of any group of adults living in urban communities in a temperate zone would be expected to yield the following frequencies of isolations from the nasopharynx:

Streptococcus pneumoniæ	20–40%
Hæmolytic streptococci	5–15%
Hæmophilus influenzæ	40–80%
Neisseria meningitidis	5–20%

There is a seasonal trend, the general carrier rate tending to fall at any season in association with increasing sunshine and decreasing relative humidity; hæmolytic streptococci show the converse as they were isolated slightly more frequently in hot and dry than in cold damp weather; the meningococcus carrier rate remained relatively steady. The figures suggest that every person examined regularly would have harboured at one time or another within the period of six years *Hæm. influenzæ* and one or other type of the pneumococcus; about three-quarters would have harboured the meningococcus and a hæmolytic streptococcus. Had the examinations been more frequent there is little doubt that each of the pathogenic bacteria under study, and many of the different types within those species, would have been detected at one time or another in each person. The subsidiary report by Rosher and Cole (1939) indicated that whilst *Hæm. influenzæ* was largely confined to the nasopharynx in the summer months, there was a tendency for it to increase the territory it occupied during the late winter and early spring; during this latter period it extended downwards into the trachea and bronchi. There was some suggestion that a similar increase in the area of the respiratory mucosa colonized was associated with certain virus infections, irrespective of the season. There is, thus, a widespread distribution of certain potentially pathogenic bacteria in the absence of overt clinical disease and accessory factors influence their extension and possibly the production of actual infection.

The study of the distribution of potentially pathogenic bacteria in domestic animals has not been so extensive nor so prolonged. In many cases it has been confined to a single examination of groups of animals. An instructive report on the persistence of *Strept. agalactiæ* and its spread in dairy herds has been issued under the direction of the Agricultural Research Council (1944). This organism may be recovered from the milk of cows that show no clinical evidence of mastitis and a high infection rate may be associated with a relatively low incidence of the disease. It was subsequently shown that one single test gave no adequate picture of the distribution of *Strept. agalactiæ* in the milk or on the teats. It was isolated from 38·8% of 16,482 samples of milk and from 23·1% of 5,433 teat swabs but when cattle in nine herds were examined at approximately weekly intervals over periods from two and a half to six months a clearer picture emerged. The proportion of cows in these herds which at one time or another yielded *Strept. agalactiæ* in the milk or on the teats varied from 35·6 to 100% in the former and from 45·7 to 100% in the latter site. The evidence here is that if milk samples and teat swabs are examined from all cattle in such herds

at weekly intervals, the percentage of animals that on one or more occasions are found to harbour *Strept. agalactiæ* in either situation rises rapidly, and that within a few weeks or months may reach or approximate to 100%. Other pathogens capable of causing mastitis have been recovered from normal healthy cattle (Francis, 1941*a*). The percentage in each case was low, ranging from 4 to 9%. This observer isolated *Corynebacterium pyogenes* from 18 of 100 pairs of bovine tonsils which accords with other observations on the ubiquity of this bacterium in certain animal species. It has been isolated from the nose of healthy sheep (Bosworth and Lovell, 1944) and from specimens of mucous membrane of the mouth of cattle (Ochi and Zaizen, 1936). Sporadic cases of infection with this organism occur frequently and support the view that *C. pyogenes* is widely distributed. Summer mastitis, abscess formation and calf pneumonia often develop with no evidence of the introduction of this bacterium from outside and *C. pyogenes* is a common secondary invader in foot and mouth disease (Weinberg *et al.*, 1938), in Pasteurella infections (Lovell and Hughes, 1935), in the lungs of calves born prematurely because of Brucella infection and in calf pneumonia following *Actinobacillus actinoides* infection (Smith, 1921, 1925). A hæmolytic cocco-bacillus, which is allied to the Pasteurella group and credited with causing rhinitis and pneumonia in calves and sheep has also been isolated from the nose and trachea of healthy sheep (Bosworth and Lovell, 1944). Other examples of the distribution of potential pathogens in or on the tissues of healthy animals may be cited. Pneumococci have been isolated from the nasal cavities of guinea-pigs (Neufeld and Etinger-Tulczynska, 1932). *Erysipelothrix rhusiopathæ* is commonly recovered from the tonsils of pigs and recently Taylor (1949) has recovered Johne's bacillus from 37 ileocæcal lymph nodes of 243 cattle.

We can therefore show to our satisfaction that many potential pathogens, and inferentially many others, are harboured by normal healthy men and animals and that one single examination yields an imperfect picture of the true incidence. There should therefore be no hesitation in accepting an epidemiological hypothesis in the absence of cases of overt clinical disease; the causal organism may be more widespread than one series of observations would lead us to expect.

(B) *The resistance of normal individuals to bacterial pathogens.*—

It is difficult to judge the resistance of normal healthy men and animals to a particular infection except by direct experiment. The activity of the phagocytic cells of the body has been well studied and the existence of a unified reticulo-endothelial system is accepted. It is, however, not so easy to estimate the resistance of individuals in the field except by the examination of body fluids and secretions. Specific antibodies play an important, though not the only, part in natural resistance to bacterial infections. The presence of apparently normal antibodies must be correlated with other facts and for this purpose they may be separated into three divisions:

(1) Those bactericidal substances and antibodies which are apparently strictly normal and for which no explanation other than a genetic or developmental one is available.

(2) Those which are probably the result of a stimulus provided by exposure to antigenically allied bacteria or possibly to some other substances chemically or antigenically similar.

(3) Those induced by exposure to the specific bacterium and resulting in a subclinical or latent infection.

(i) Normal serum has a marked bactericidal effect on various organisms, particularly the Gram-negative ones and in many cases it is due to the combined action of complement and a heat-stable factor which does not appear to be related to a specific immune body (Gordon and Hoyle, 1936). Leukins, obtainable from leucocytes

and β-lysins, substances present in serum, are also bactericidal for many strains of bacteria. The bactericidal properties of serum vary according to the species of animal; rabbits, although relatively susceptible to anthrax, exhibit in their sera a bactericidal property for the anthrax bacillus; fowl serum has little effect on this organism and yet the fowl is relatively resistant to the disease. Such facts as these cannot as yet be explained to our satisfaction. Lysozyme is a bactericidal substance present in tears and other secretions, and this suggests that similar substances effective against other organisms may be present in tissues and body secretions.

(2) Surveys of the antibody content of the sera of man or animals living under natural conditions reveal that many samples contain substances that react in the same way as specific agglutinins or antitoxins. Bürgi (1907) found agglutinins for many species of bacteria in the sera of dogs, birds, sheep, horses, goats, cattle and man. Agglutinins against the "H" antigens of 7 different Salmonella were found in the sera of a large number of cattle, sheep, pigs and horses by Lovell (1932) and further examinations were made of the agglutinins against both "H" and "O" suspensions (Lovell, 1934); most of the sera from cattle, pigs, sheep and horses agglutinated many of the suspensions to a low titre whereas, in general, most of the rabbit sera failed to agglutinate any of the suspensions tested. Absorption tests showed the specificity of these agglutinins and there was some evidence of their increased frequency with advancing age. They were probably due to stimulation by bacteria which are normally present in, or on, the tissues of the animals and although not Salmonella bacteria, were in some way antigenically similar. Many examples of the immunological and chemical association of apparently unrelated bacteria are known, e.g. Friedländer's bacillus and pneumococcus Type II, some types of *Pasteurella pseudotuberculosis* and Salmonella, certain strains of *Bact. coli* and Salmonella. Two fæcal strains of *Bact. coli* isolated from the pigs tested stimulated the production of agglutinins for Salmonella in rabbits.

A similar picture emerges from the study made of the agglutinins for *Pfeifferella mallei* in normal horse sera. The median titres obtained with 314 samples were: 1:320 and 1:640 respectively against two different suspensions. All of a few samples from cattle, pigs, goats and rabbits also contained similar agglutinins though to a lower titre. Glanders is a disease of horses, and the history of the horses from which the sera were obtained revealed the extreme improbability of their ever having been in contact with the disease. At the time of the investigation (Lovell, 1935) no case of glanders had occurred in Army horses in this country for well over ten years and the majority of the horses were Army ones obtained from this country or Eire and were less than ten years of age. Furthermore the incidence of glanders in civilian horses had been negligible for some years previous to the investigation. The frequency distribution of these agglutinins, therefore, gave no indication of the incidence of the disease nor of latent infection; the sera of animals which do not normally suffer from glanders, viz. cattle, pigs, goats and rabbits, also possessed agglutinins for *Pf. mallei*. The most reasonable explanation for their presence is that they too were stimulated by the presence of some common substance antigenically related to *Pf. mallei*. Other authors have recorded similar experiences and found no adequate explanation for the presence of these natural agglutinins (Gibson, 1930, 1932; Timmerman, 1930).

Although natural hæmolysins and natural hæmagglutinins develop during growth, and a correlation exists between the increase of natural agglutinins and serum globulin, there is a balance of evidence that the formation of some of the antibodies discussed is due to external stimuli. Their immunological significance is hard to assess and in general they appear to have little or no protective value; it is possible that they may act as the "primary stimulus" rendering the individual more sensitive

to the specific antigen in question. Cows and horses possess agglutinins against *Pf. mallei* in their sera yet their respective susceptibility to glanders is very different. Cattle, pigs, horses and sheep contain agglutinins against Salmonella bacteria in their sera but here again, there is a variability in their susceptibility to Salmonella infections not revealed by serological tests.

(3) There is little doubt that some of the antibodies detected in a survey are due to the stimulus provided by specific infection; in many cases a subclinical one. Some of the antitoxins fall into this class, such as diphtheria and scarlatina antitoxin in man and *C. pyogenes* antitoxin in animals. It is well established that detectable amounts of diphtheria and scarlatina antitoxins are present in about 50% of children during their first few months of life, probably transferred passively from the mother. This resistance is short lived, and after a phase of susceptibility to infection the passive immunity is replaced by an active one caused by exposure to infection. There is thus a gradual process of immunization and after the age of 20 only 10-15% of individuals are Schick or Dick positive (Zingher, 1923, 1924). A survey of the *C. pyogenes* antitoxin content of the sera of different species of animals revealed that the mean antitoxin content of cattle sera was 83·0 "x" units per c.c. and the values obtained with sera of other species were: pigs 84·4, sheep 25·6, pigs 51·5, horses 13·7, man 1·2 and rabbits 0·7 (Lovell, 1939). The higher values and a greater variability occurred in the sera of cattle, sheep, goats and pigs, animals which are naturally and frequently infected with *C. pyogenes*. An intermediate position was occupied by horses, in which *C. pyogenes* infections are almost unknown whilst the sera of rabbits and man, species which are rarely or never attacked, had extremely low values. An association existed in cattle between increasing age and a higher mean and greater variability of antitoxin values; still higher values were observed in animals naturally infected or injected with toxoid. If one links all these facts then one is forced to accept the view that the antitoxin present is specific and that *C. pyogenes* is widely distributed amongst the healthy cattle, pig, sheep and goat population and that infection with this organism is frequently endogenous.

(C) *Environmental and subsidiary factors which initiate infective diseases and break down natural immunity.*—

Immunity is a misleading term and actually means a study of all those factors which disturb a fluctuating equilibrium existing between a parasite and its host. Ryle (1948) asks us to recognize the fact that no disease has a single cause although many diseases have a specific one. Bacteriologists have, in the past, been too absorbed with the specific causes of disease, and clinicians with the alleviation of symptoms; neither has enquired too closely into the actual ætiology of diseases. The examination of body fluids and secretions during life and the study of tissues after death may tell us much of specific causes but little of the factors leading to the morbid changes and to death. Unless we recognize those factors which initiate an infection, thereby giving the specific parasite the upper hand, diagnosis is incomplete and prevention is applied empirically. The laboratory may furnish much but not enough for our needs; field surveys and examinations of groups of animals and men must be made; analyses of the conditions whereby infective diseases arise will indicate future lines of research, first by the formulation of a hypothesis which can then be tested under controlled conditions.

The evidence I have presented concerning the ubiquity of potential pathogens, and inferentially others not yet found, suggests that the onset of many infective processes is conditioned by other factors than mere exposure to infection. Special "epidemic strains" may start an epidemic when they are introduced into a closed or semi-closed community, but how have these special strains acquired the status of "epidemic strains"? Presumably by attacking those individuals which are most susceptible first, and their virulence is then increased by natural passage. The

mechanisms which enable this change of virulence to develop may well be similar to those which convert a latent infection into an overt clinical condition. A study of subsidiary factors may supply an answer to both aspects of medicine. An investigation of the relationship between the distribution of a pathogen, and the specific antibody content of the sera of groups of men and animals, is needed in many cases ; we know little of this relationship in diphtheria in man. The relationship of the distribution of normal agglutinins and the carrier rate of the relevant bacteria, would be more difficult to assess because different stimuli are probably responsible for the agglutinins; in general, normal agglutinins are less specific than the antitoxins.

A large volume of literature on the relationship of nutrition and infection is available but as Gell (1948) has said, it is not easy to demonstrate that mass starvation has been an important factor in the genesis of epidemics of human disease. Famine is not the only feature in such situations, which include overcrowding, insanitary conditions and mass movement of populations. Little is known of the effect of starvation on the bodily defence mechanism; protein starvation may depress the antibody-response to infection, and this may be linked with the inability of young stock to respond well to an antigenic stimulus, especially in ruminants which depend upon colostrum for their protein during their first few days of life. Colostrum supplies a deficiency in protein and probably other substances as well. No widespread epidemics have occurred in man during the last ten years which can be linked with the excessive undernutrition experienced in some areas. Some specific deficiencies are known to predispose to certain infections and this is shown by the relationship existing between a nicotinic-acid-deficient diet and bacterial invasion of the gut wall and the associated lymph glands in pigs (Chick *et al.*, 1938*a*, *b*). On the other hand in some other infections, the strong well-grown individuals are more susceptible to disease; blackleg and anthrax in cattle are more frequent in young well-grown cattle than in the lean ones; foot and mouth disease is more severe in well-grown, well-nourished animals; in fact they are most susceptible when in prime condition and at the prime of life (Edwards, 1937). It may be that the preference viruses have for growing in actively dividing cells may have some bearing on this observation. The nutritional status may play some part in the epidemiology of poliomyelitis as the healthy well-nourished appear to be more frequently attacked than the ill-nourished. Thompson (1949) suggests that the mode of life and personal habits are possibly the deciding factors. Dust-borne infection may be important and that in many sufferers there has been a neglect of personal hygiene; this might explain why the older schoolgirl, the most fastidious member of a community, usually escapes lightly. That nutritional factors influence the response to injections of toxin and toxoids has been shown experimentally in sheep by Mackie *et al.* (1932) and in guinea-pigs by Hartley (1948).

The pharmacological effects of substances in the diet may exert some influence, for example: outbreaks of enterotoxæmia in sheep due to *Clostridium welchii* Type D frequently follow the transfer of a flock from one type of pasture to another, and their return coincides with the cessation of cases of disease. Is there some substance in the diet of the new pasture which facilitates the proliferation of the clostridia? Ferguson (1948) has demonstrated the muscle-inhibitory activity of clover juices and Quin and van der Wath (1938) showed that small doses of cyanide cause complete stasis of ruminal movements in sheep. Various clovers contain cyanogenetic glucosides and one is apt to wonder whether these observations may have some bearing on the onset of enterotoxæmia in sheep.

Certain well-defined factors undoubtedly assist bacteria to establish themselves and proliferate in particular tissues. The influence of tissue damage, soil, calcium salts and proteolytic bacteria in the development of gas gangrene and other clostridial infections is well recognized. The part played by *Fasciola hepatica* in the germination

of spores of *Cl. œdematiens* thus leading to black disease of sheep is also well known. The non-specific non-living agents are difficult to find and to assess and may be associated with a particular habit of man or animals. A deficiency in the diet available may determine such a habit as in lamziekte in cattle and sheep. The toxin of *Cl. botulinum* is the specific cause of this disease but this alone does not explain its ætiology nor provide a method for prevention. A lack of phosphorus in the soil and vegetation leads to a condition of osteomalacia; styfziekte, a stiffness and lameness, follows and in an attempt to overcome this the affected animals have a craving for chewing the bones of the dead; if these are infected with *Cl. botulinum*, a common soil organism, and its toxin, then intoxication occurs with disturbance of deglutition and mastication as well as a more general paralysis. A simple method of prevention presents itself; bone meal or other forms of phosphate are included in the diet and animals cease this habit.

Some interesting lessons can be learned and fresh problems formulated by a study of mastitis in cattle. The disparity between the carrier rate of *Strept. agalactiæ* and cases of contagious mastitis has already been referred to. Hughes (1949) pleads for a recognition of this disparity and for a critical reassessment of many present-day methods of hygiene designed to control the spread of infection. Francis (1941, *b*) considers that the conformation of the teat may assist bacteria to penetrate mammary tissue and that evolutionary and involutionary changes which depend on fluctuations in the concentrations of hormones may also influence the susceptibility of udder tissue to invasion. That skin and teat lesions have some effect has been demonstrated in the infection of cows with *Strept. pyogenes* of human origin (Bendixen and Minett, 1938). The milking machine plays a part in other forms of streptococcal mastitis (Neave, Sloan and Mattick, 1944) and a high incidence has been recorded in herds when the vacuum readings of the milking machine have been too high, or the gauge has been faulty. Mastitis has been produced experimentally by using a high vacuum and the incidence in a herd reduced by a low vacuum. The specific bacteria isolated—*Strept. dysgalactiæ* or *Strept. uberis*—cannot be cited as the whole reason for the mastitis which develops.

The story of staphylococcal mastitis is also far from complete; *Staphylococcus aureus* may cause a mild chronic catarrhal type, a chronic fibrous form or an acute gangrenous inflammation. What factors are responsible for this variation? What is the association between the latter form and parturition? Summer mastitis—the specific cause of which is *C. pyogenes*—occurs most frequently in dry cows and heifers at grass and flies have been held responsible for its spread. This seems unlikely, when we consider the number of cattle which carry the organism. Irritation of udder tissue by flies may aid the migration of the organism to the mammary gland but why does it occur in the non-lactating gland more frequently than in the lactating one? The variable annual incidence, apart from the seasonal incidence, cannot be explained by the variation in the number of immunes and non-immunes at risk. All but 3 of 575 samples of bovine sera examined, contained detectable amounts of *C. pyogenes* antitoxin and this makes such an explanation unlikely. Recourse to field studies and field surveys might indicate profitable lines of research and reveal the actual problem which needs solution. Summer mastitis is still a menace to our dairy herds in spite of our knowledge of the specific cause; its ætiology is obscure.

A specific cystitis and pyelonephritis in cattle is caused by *Corynebacterium renale* and the theories which have been postulated as to why the organism localizes itself in the kidney medulla are, at the moment, the subject of laboratory investigation. There is, however, insufficient knowledge as to why certain cows in a herd suffer and others escape. It has been suggested that there is an association between it and pregnancy; nearly all dairy cattle are in some stage of pregnancy for three-quarters

of each year during their reproductive life. Adequate field studies might tell us whether the onset of the disease is linked with a particular stage of pregnancy and thus lead to an analysis of the factors associated.

Latent virus infection, which is accepted with some viruses, is now credited with a role in the ætiology of certain tumours. A simple working hypothesis of their origin is that the action of a chemical carcinogen prepares cells to accept a latent virus already in existence in the bodies of normal animals (Imp. Cancer Res. Fund, 1949). A similar theory could well be applied and thereafter tested as to the origin of many of the obviously infective diseases.

Many other examples similar to those dealt with exist and one which at the moment is being studied concerns those bacteria which, although non-pathogenic for adults, may cause disease and death in the newly born. Spence (1941) stated that " an organism such as *Bacterium coli* which is relatively innocuous to older children may cause a rapidly fatal illness in a newborn infant and an investigating bacteriologist with fixed ideas of what are pathogenic organisms may be led astray". This outlook is not new in the field of animal pathology, for it has been known for fifty years that *Bact. coli* is capable of killing calves. Similar organisms are now credited with causing diarrhœa in babies (Cass, 1941; Giles and Sangster, 1948; Taylor *et al.*, 1949). In enquiries of this nature, the environment of the young is of prime consideration. The development and nurture of a fœtus are gradual until it is expelled from the uterus, and this sudden change of environment is largely provided for by the transference of a passive immunity to the prevailing bacterial flora, either by the placental vessels or through colostrum, according to the species of animal concerned. Should there be a sudden change of environment of the mother during the latter days of pregnancy, or of the newly born shortly after birth, then the young animal or baby is exposed to a different bacterial flora, which may be harmless to the mother but fraught with danger for the young. The immunity passively transferred may be effective against the bacteria of the previous environment but not necessarily against these now encountered. The diarrhœas of young babies and calves are frequently associated with *Bact. coli*; in lambs it is *Cl. welchii* Type B. In calves and lambs the provision of colostrum, and especially colostrum containing antibodies against the specific and prevailing bacteria, is of paramount importance. Lamb dysentery can be controlled by active immunization of the mother, and the immunity engendered is transferred to the young and this protects it during the period of susceptibility. Owing to the variable antigenicity of *Bact. coli* this method of control is not applicable for "white scours" in calves. Other means have to be sought for, and field studies may indicate the most profitable paths. There is a correlation between the date of calving and the loss of calves; in dairy herds there is a greater loss in the spring, possibly associated with a dietary deficiency in the mother during the winter months preceding parturition (Lovell and Hill, 1940). My colleague Mr. F. W. Withers, who is making a study of the mortality of calves under the direction of the Agricultural Research Council, has permitted me to quote some of his unpublished observations. He finds a correlation between the heavy losses experienced in some dairy herds and an irregularity of non-lactating periods in the cows. A great variability in temperature also appears to favour losses; for example, the month of March is noted for a variation ranging from mild warm weather to cold frosty spells and this is more hazardous for young stock than continued cold weather. Such observations are only possible in the field, and it is important that in these infective conditions, which beset the human population as well as our flocks and herds, such field studies be made. The specific infective agent is one factor in the ætiology of a disease, and a fuller understanding of the ætiology of any condition paves the way for its prevention, often by simpler means than by specific immunization.

SUMMARY

It has been my endeavour to point out how difficult it is to estimate the extent of the carrier rate of pathogenic bacteria in man and animals. In some cases it can be shown by frequent examinations, that certain pathogens are present in or on the tissues of all the individuals examined. It is possible that this state of affairs exists with other pathogenic bacteria, and inferentially with viruses; in many instances our examinations have not been made sufficiently extensive, nor frequently enough, or the technique available is not adequate for the isolation of the bacteria unless they are present in large numbers. With some bacteria this viewpoint has been supported by a serological examination, and we find that all the members of a community acquire, by natural means, a degree of resistance to a specific bacterium or its toxin. In other cases, especially when the serological test employed is the agglutination reaction, the presence of antibodies bears no relationship to the carrier rate. We have then to consider the probability that the stimulus is provided by other bacteria or substances which are antigenically related, and the possession of such antibodies may not mean the enjoyment of any increased specific resistance. When the natural history of some infective diseases is examined we are faced with many questions which at the moment we are unable to answer. By what means are the potential pathogens, which are so commonly found, converted to "epidemic strains" and are then capable of inducing infection in a large number of individuals at risk?

This increase in virulence may be associated with a reduction in the resistance of one individual, thereby enabling the bacteria to proliferate; passage through successive hosts enables it to dominate the bacteriology of a particular herd or area. Is this the mechanism involved in the production of "epidemic strains"? If so, then recognition of those factors which contribute to a reduction in the resistance of the host is called for. There is some evidence to suggest that a similar process is implicated with bacteria which are relatively harmless to adults but assume a pathogenic role in the young. Such problems as these may be solved by a consideration of the subsidiary causes which are involved in infective diseases and these can be determined by careful observations made in the field; that is, by examination of the conditions of life enjoyed by groups of people and herds of animals. The so-called "nutritional status" is not exact enough, as the animal in a good state of health appears to be more prone to some infections than one in a poorer state. The reduction in the major epidemics of the past is likely to be accelerated in the immediate future by the success achieved with modern therapeutic agents and the importance of the specific infective agent will be decreased; more attention will then be paid to the influences of climate, season, diet, habits and other factors in initiating and correspondingly in the prevention of disease. These problems become physiological rather than bacteriological but the physiological problem cannot be enunciated until we have more information of the natural history of diseases. Furthermore our horizon stretches beyond that of preventive medicine; it is the aim of social medicine to provide conditions whereby people may enjoy the fullness of life. This is a positive outlook and may be applied to our animal population too; the well-being of domestic animals is one objective of students of comparative medicine, as animals which are in excellent health and condition provide the community with good food and other necessities. Such a state may be achieved not only by the application of discoveries made in laboratories but by paying adequate attention to observations of the clinician and field worker.

> "Then shall two be in the field; the one shall be taken, and the other left. Two women shall be grinding in the mill ; the one shall be taken, and the other left."—(Matt. xxiv, 40-41.)

This occurs in medicine to-day and one day the reasons may be revealed to us.

Cortisone (Compound E) and Adrenocorticotrophic Hormone in Rheumatoid Arthritis

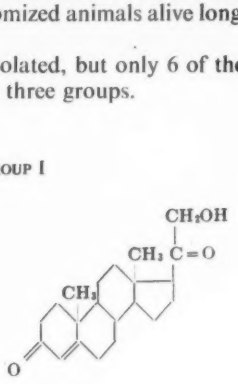
By OSWALD SAVAGE, O.B.E., M.R.C.P.

WITH some fifty other physicians from all over the world I was privileged to see the work on Cortisone at the Mayo Clinic in June 1949, and it so happened that by chance I was called out by Dr. Hench to examine one of the two cases we saw both before and after treatment. There is no doubt in my mind, or I should imagine in the mind of anyone else who was there, of the remarkable changes effected by this drug in rheumatoid arthritis.

As one would expect from such a team as Hench, Kendall, Slocumb and Polley (1949) the work has been most carefully checked and controlled, and the cases which we saw were suffering from severe active rheumatoid arthritis of some standing. We saw two cases before treatment, one with Cortisone and one with A.C.T.H., and the change effected by only two and a half days' treatment was extraordinary. One woman of 55 years had suffered for three years; she could hardly walk and it took her two hours before she could do her hair in the morning. Her sedimentation rate was 67 and she was taking 60 grains aspirin per day. After even such a short period of treatment as two and a half days she was free from pain and we saw her walk normally. She felt a sudden improvement nine hours after the first injection—as she put it "I feel a load taken off"; another remark she made was "I can do anything right away".

The history of the work is a fascinating one, for during the war it was rumoured that the German pilots were being given injections of suprarenal extract to increase their fighting efficiency and so momentum was given to work proceeding on the cortical substances.

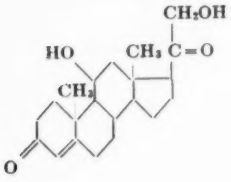
For many years Hench (1949) has been studying the reversibility of rheumatoid arthritis and eventually discarded the microbic theory, as he said in his Heberden Oration in this country last year, and turning to the biochemical possibilities he concluded that the "antirheumatic substance X", as he called it, might be an adrenal hormone.



If we are to understand the work done on Cortisone we must study the present-day work on the adrenal steroids.

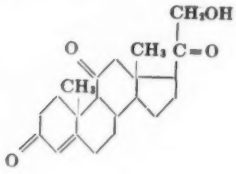
All this work is comparatively recent and dates from the 1930's for before that time it was impossible to keep adrenalectomized animals alive long enough to examine the effects of giving cortical substances.

So far 28 adrenal steroids have been isolated, but only 6 of them are active as far as is known. These 6 can be divided into three groups.

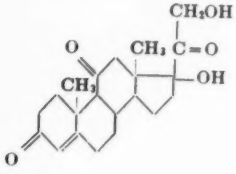


GROUP I

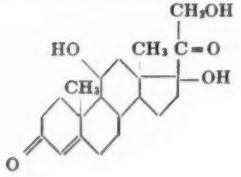
Desoxycorticosterone



GROUP II

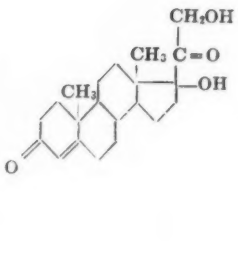


Corticosterone (Compound B)



Dehydrocorticosterone (Compound A)

17-Hydroxy-11-dehydrocorticosterone (Compound E)



17-Hydroxycorticosterone (Compound F)

GROUP III

17-Hydroxy-11-desoxycorticosterone (Compound S)

Amorphous fraction

The first contains desoxycorticosterone alone. The second contains corticosterone, dehydrocorticosterone, 17-hydroxy-11-dehydrocorticosterone and 17-hydroxycorticosterone. You will see these are all oxygenated at the 11 position and because of this are called 11 oxysteroids. It is this group with which we are principally concerned because it contains Compound E now called Cortisone. This group is also referred to as the glycocorticoids because they are chiefly concerned with carbohydrate metabolism; sometimes they are just called corticoids. The third group is composed of what is left over. There is 17-hydroxy-11-desoxycorticosterone or Compound S which has little effect on carbohydrate metabolism and when the crystalline fractions have been extracted there remains a highly active residue called the amorphous fraction which has been little studied.

Desoxycorticosterone or its acetate D.O.C.A. has been the most studied of these active steroids, as so far it is the only one for which a cheap method of synthetic production has been available and it has been used chiefly for Addison's disease. In 1937 Steiger and Reichstein announced its synthetic preparation from stigmasterol and a little later Reichstein and Van Euw (1938) recovered it from the adrenal cortex. Desoxycorticosterone causes a marked retention of sodium, chloride and water and increases the excretion of potassium and phosphorus; however, it exercises hardly any effect on carbohydrate metabolism. In Addison's disease it will restore the blood electrolyte pattern to normal and elevate the blood-pressure and is life-saving in Addisonian crises. Its continued use can result in œdema and heart failure.

Our group, the 11-oxysteroids containing corticosterone, dehydrocorticosterone, 17-hydroxy-11-dehydrocorticosterone (Cortisone), 17-hydroxycorticosterone, are concerned chiefly with carbohydrate metabolism.

As early as 1930 Britton enunciated the theory that the "prepotent function" of the adrenal cortex was to regulate carbohydrate metabolism. He observed that the adrenalectomized animals developed acute hypoglycæmia and low glycogen levels and that when normal fasted animals were given large doses of cortical extracts there was an increase in blood sugar and in both liver and muscle glycogen. These views were met with misgiving but they now fit into the picture of established fact.

In 1936 Mason, Myers and Kendall, and in 1937 de Fremery and his co-workers isolated corticosterone, now called Compound B, and dehydrocorticosterone, now called Compound A, both extracts of the adrenal cortex, in crystalline form. They found they could maintain adrenalectomized animals in good condition by giving these substances.

Kendall (1941) at the Mayo Clinic isolated 17-hydroxy-11-dehydrocorticosterone from the adrenal cortex and called it Compound E; a few weeks later Pfiffner and Kamm (1942) in Switzerland isolated the same compound and called it F. This caused some confusion and the substance is now known as Cortisone. Another compound called S has also been isolated and has the chemical name of 17-hydroxy-11-desoxycorticosterone but having no oxygen at C 11 it has no effect on carbohydrate metabolism.

The four compounds, A, B, E and F have a marked effect on carbohydrate metabolism and E, or Cortisone, is by far the most active in this respect. Compound F is so unstable it is difficult to study. Thorn has divided this group into Compounds A and B, the 11-oxysteroids, and Compounds E and F, the 11-17-oxysteroids, which have an OH group at the 17-position.

They cause an increase in the blood glucose levels and the liver glycogen stores. They cause an increased conversion of protein to carbohydrate and also an increase in the renal clearance of uric acid, resulting in the excretion of large quantities of urates both in normal subjects and patients with gout.

Compounds E and F, the 11-17-oxysteroids, have an effect on the lymphoid tissue which is shown by the decrease in the number of circulating eosinophils and also lymphocytes.

The other substance which has been tried is A.C.T.H., the pituitary adrenocorticotrophic hormone. It has recently become available in sufficient quantities to study its effect on the secretion of adrenal steroids in man. It causes a profound fall in circulating eosinophils and a rise in the urinary uric acid excretion. It causes sodium and chloride retention, a rise in blood sugar level, an increase in the excretion of 17-ketosteroids and a rise in the level of circulating 11-oxysteroids. In fact in man it causes increased secretion of adrenal steroids, giving the effects observed with the crystalline adrenal steroid preparation and of adrenal hormone therapy. In short, it reproduces the effects of Cortisone therapy in rheumatoid arthritis.

Now for the clinical effect of Cortisone in more detail. The clinical improvement may start after only four hours but it is usually felt in the first day or two. The first effect is on the stiffness and the patients say they feel as if something had been unlocked from their limbs. They lose their pain remarkably quickly and joints which were tender on firm pressure become painless. The swelling does not, of course, go so quickly, but I understand that mildly contracted joints have straightened out on Cortisone though I did not see this myself.

These patients get a remarkable euphoria and very often lie awake for the first night or two, free from pain and excitedly planning a future free from arthritis. After this phase they usually fall into a sleep of exhaustion. They acquire a ravenous appetite and eat so much that later they may have to be dieted to avoid obesity.

At the International Congress of Rheumatic Diseases in New York last June Dr. Hench showed a film of a patient whom we later met at the Clinic. His joints were tender to firm pressure and he could hardly get up and down steps. After nine days' treatment the film showed he had lost his tenderness and could go up and down the steps quite normally. He offered to run for the film outside the hospital but as there was snow on the ground he was only allowed to do so in the studio.

What about the objective tests? The sedimentation rate comes down to normal but is not so rapid as the remarkable clinical improvement. As Dr. Hench puts it "the B.S.R. and the symptoms are travelling in the same train but not in the same carriage".

The anæmia of rheumatoid arthritis responds to Cortisone alone and no iron or other medication is required. The albumin-globulin ratio reverts to normal.

It was perhaps a stroke of genius which led Hench to try the first case on what might be considered a tremendous dosage for hormone therapy, because if he had not done so he might have missed the bus entirely. Cortisone does not work except in large doses and the cases which we saw which responded so remarkably had 300 mg. the first day and 100 mg. subsequently. It is given by injection and the drug is so expensive and precious that every precaution is taken to see that none is wasted.

With A.C.T.H. the dosage is smaller but given more frequently and the patient we saw treated had 50 mg. t.d.s. the first day and 25 mg. t.d.s. the second day.

I believe the side-effects have been rather over-emphasized but as Hench says: "This stuff is dynamite" and it is extremely important that they should be noted and publicized, because, when this drug becomes available it should not be used except under the most carefully controlled conditions in hospital.

The Side-effects

These can be discussed under two headings: (1) Those due to pituitary upset; (2) Those due to the upset of the electrolyte balance.

The pituitary upset gives rise to Cushing-like changes which are manifested by a rounding of the facial contours, hirsuties with a growth of hair on the face, purple

striæ, comedones, amenorrhœa and depression. These occur usually after about two weeks but in one case began earlier in treatment. In another case we saw that well-marked purple striæ had been produced across the buttocks.

The upset in the electrolyte balance may give rise to œdema due to the sodium chloride retention and to alkalosis.

A.C.T.H. has given rise to severe headache and vomiting on occasion.

Cortisone and A.C.T.H. have to be continued indefinitely; unfortunately directly the drug is stopped the symptoms return within a few days and the sedimentation rate rises again. It must be remembered that only severe cases have been treated so far but it does look as if treatment has to be continued.

The difficulties of production are immense and 39 long and difficult steps have to be passed before a minute yield of Cortisone is gained from desoxycholic acid. Apparently with the finding of *Strophanthus sarmentosus* this number has been reduced to 17 but the chemists still face a most difficult procedure. Owing to these difficulties, only 17 cases had been treated by June 1949 at the Mayo Clinic though some of these had been under treatment and control periods for over six months. It may be said that this is too few to establish the remarkable claims made, but all except one had responded dramatically.

One of the most remarkable moments at the International Congress on Rheumatism was when, after Dr. Hench and Dr. Kendall had delivered their papers on Cortisone, five physicians who were known to be extremely critical of any claims for the successful treatment of rheumatoid arthritis, who had been invited by the Mayo Clinic and each given sufficient to treat one case under his own control, came on to the platform and confirmed the remarkable effects of this drug in their own cases.

Apart from applauding the authors and their brilliant piece of research we should consider what advance has been made in the study of rheumatic diseases.

To my mind there are two main points of progress even before the drugs are available to study on our own cases. Point 1 is that it has been shown for the first time that the progress of rheumatoid arthritis is rapidly reversible by a drug. Dr. Hench has pointed out that the condition is reversible in pregnancy and sometimes in jaundice and now a drug has been found that can do the same thing. Point 2 is, I believe, equally important: we have a yardstick to evaluate treatment. The trouble with the treatment of rheumatoid arthritis has been that there are so many forms that improve the patient up to a point. Some are better than others and I believe myself that gold is one of the good ones but it is almost impossible to demonstrate that any one of ten or more treatments is better than another.

The rapid and dramatic improvement with Cortisone and A.C.T.H. is most striking compared with anything we have seen before, or any other present-day treatment of rheumatoid arthritis.

I hope I have made it quite clear in this short talk that all the credit for this work should go to the research team at the Mayo Clinic, Drs. Hench, Kendall, Slocumb and Polley.

Dr. Raymond Greene: *Some Endocrinological Aspects of Rheumatoid Arthritis.*

The realization of the rôle of the adrenal cortex in the ætiology of rheumatoid arthritis seems to have come with shock-like suddenness to the profession at large. In fact, however, many workers on both sides of the Atlantic have been studying the question for some years (e.g. Coke, 1945, and Bassi, 1946). Much of this work is doubtless unfinished and therefore still unpublished, but as early as 1944 Selye and others claimed to have produced arthritis in nephrectomized rats with D.C.A. combined with a high salt intake. His results were disputed by Harrison in 1946, but whatever may be the ultimate judgment on Selye's results his paper focused further attention upon the adrenal cortex, an attention which became still more intense with the publication of his monograph on the General Adaptation Syndrome in 1946.

My own interest in the subject began some twelve years ago. Whereas Hench and his colleagues reached their inspired guess by a study of two conditions (jaundice and pregnancy) which alike may cause a temporary remission of the disease, I approached the problem by a different path, preferring rather to seek the common factor in a number of apparently distinct conditions often associated with the onset of the disease—puberty, lactation, the climacteric, psychological strain, infection and perhaps thyrotoxicosis. The hypothalamic-endocrine system appeared to be a possible connecting link between these apparently various exciting causes, and, within this system, the adrenal cortex the most likely area to explore.

In April 1944 a patient was admitted under my care to Tindal House Emergency Hospital, Aylesbury, suffering from extremely severe rheumatoid arthritis, his condition strongly resembling that of the next patient to be described. I treated him with Eucortone, D.C.A., and anterior pituitary corticotrophic hormone without producing any improvement. Despite later recourse to all orthodox methods he died some months later. In the light of the Mayo Clinic report it seems likely that the sample of corticotrophin was inactive. The difficulty of obtaining corticotrophin caused me for some time to concentrate my attention on the possible effects of whole adrenal extracts and of D.C.A., both of which I found to be ineffective. These are, I gather, under trial in the U.S.A. I can assure workers there that their efforts are vain.

On November 25, 1946, a labourer aged 28 was admitted to the Metropolitan Hospital in an apparently moribund condition. In addition to rheumatoid arthritis of a greater severity than I had previously seen, he had severe pemphigus.

[Here Dr. Raymond Greene described in detail the history, investigations and the general measures of treatment given.]

In addition to these general measures, adopted of necessity and in the full realization that they seriously vitiated the scientific value of the experiment, I set up an intravenous procaine drip, a course which demands some explanation.

I had abandoned the use of whole cortical extracts and of D.C.A. as useless and the difficulty of obtaining corticotrophin in quantity had caused me to seek other methods of stimulating the adrenal cortex. It appeared possible (Ungar, 1944) that procaine, perhaps acting by way of the anterior pituitary, might be such a substance. This point will be the subject of a separate communication.

Within two days of beginning treatment with procaine improvement was noticeable. His joints became less painful and could be moved gently through a few degrees without pain. His morale, which had sunk to a very low ebb, improved. The pemphigus ceased to spread and the E.S.R. dropped from 90 mm. to 40, and at the end of a fortnight of treatment to 16 mm. Apart from this last rather unreliable criterion it might be suggested that improvement was due to the anæsthetic properties of procaine, a possibility which cannot be dismissed. Against such a supposition is the fact that improvement continued (though more slowly) after the cessation of treatment. By the end of December 1946 he could eat solid food and the pemphigus was clearing rapidly. In January the E.S.R. was 10 mm. and his joints were free from pain. He got up on February 8, 1947, when he was weighed for the first time. He weighed 7 st. 2 lb. (45·4 kilos) and it was thought that he had put on about two stones (12·7 k.).

Improvement continued, but very slowly, and in early March slight deterioration began, though the E.S.R. was still normal. By this time I had obtained some corticotrophin through the kindness of Dr. A. Macbeth of Organon. A course of daily intramuscular injections was begun on March 6 and continued until March 23. The daily dose was only 2–3 mg. A great improvement occurred during treatment but was not afterwards maintained. In May his E.S.R. was found to be 45 mm. On May 6 procaine injections were started again and continued until June 9. The E.S.R. dropped to 9 mm.

From that time functional improvement continued very slowly, but the disease remained inactive and he was finally discharged on December 15, 1947, with no disability other than a painless deformity of his hands. He has remained well ever since ; he is, as far as I have been able to determine, the first patient to be treated successfully for rheumatoid arthritis with corticotrophin. [Dr. Raymond Greene then demonstrated the case.]

His continued good health requires explanation. Hench's patients need continued treatment. The most likely explanation seems to be that at some time during 1947 a spontaneous remission was "due." Those who saw him on his admission are convinced that he would not, without the treatment he received, have lived to enjoy that remission. Nevertheless I remain loth to attach much significance to a "cure" produced by so many concurrent methods of treatment.

One other patient was treated successfully with corticotrophin in March 1947. The difficulty of obtaining supplies then caused me to concentrate my attention on other possible methods of producing increased adrenal cortical activity and in particular on the effects of adrenaline (Vogt, 1944), iso-propyl-noradrenaline, the antihistamine drugs, ascorbic acid, nupercaine, and procaine, substances which have an inhibitory effect on histamine release (Ungar, 1944). It is interesting to note at this point that procaine hydrochloride is the hydrochloride of the base prepared by the interaction of chloroethyldiethylamine and sodium para-aminobenzoate. Benadryl is chemically a closely allied substance. I am not ready yet to make any statement on the majority of these substances, but it may be of interest to report briefly on 12 patients, all of whom have received procaine by slow intravenous infusion.

Of 3 who received under 10 grammes, 1 showed a moderate improvement and 2 no improvement.

Of 4 who received between 10 and 20 grammes, 2 were improved to the extent of a temporary cure, 1 was moderately improved, and 1 not improved.

Of 5 who received over 20 grammes, improvement amounting to temporary cure occurred in 2, moderate improvement in 2 and slight improvement in 1.

This improvement may have been the result of the local anæsthetic action of procaine or of some other mechanism entirely unrelated to the adrenal cortex. Moreover we cannot regard the use of intravenous procaine as a serious advance in treatment. It shares with Cortisone and corticotrophin, which are far more effective, the disadvantages of affording usually only temporary relief and is, in addition, impracticable except in hospital. If, however, its effects are indeed mediated through the adrenal cortex, as Ungar's experimental work suggests, the clinical improvement produced is of theoretical interest in that it draws attention to the possibility of attaining our ends by means less difficult in practice than the use of Cortisone or corticotrophin.

My reason for suggesting that the effects of procaine are not dependent on its local anæsthetic effect now needs explanation.

It has long been a matter of interest to those concerned with both rheumatology and endocrinology that in two types of rheumatoid arthritis, Still's disease and Felty's syndrome, the joint changes are associated with enlargement of the spleen. Since 1932, a number of reports have occurred of improvement in rheumatoid arthritis after splenectomy, including one by Bach and Savage in 1940, and by Bach in 1946. In this latter report Bach drew attention to the rise in blood cholesterol in starvation, pregnancy and jaundice and after splenectomy, and pointed out that cholesterol may well be the mother substance of the sterols of the adrenal cortex. The results of splenectomy are so unreliable (Coburn and Pauli, 1935) that the operation has been abandoned. Nevertheless the hint may be worth taking.

In 1945, Ungar claimed to have demonstrated the presence of two substances in the serum of traumatized guinea-pigs. One, which he afterwards called splenin A, decreases bleeding time and the other, which he called splenin B, increases it. Splenin A increases capillary resistance and inhibits histamine release. He claimed that the release of splenin A is dependent upon a chain of events beginning with trauma, which produces an increase in the output of corticotrophin from the anterior pituitary, which causes an increase in the activity of the adrenal cortex, which in turn causes the output of splenin A from the spleen. He suggested that an increase in splenin A might be part of the alarm reaction of Selye, and stated that splenin A is present in normal human blood, whereas splenin B is not. His experiments have not yet been confirmed.

Selye having already hinted at the possibility of rheumatoid arthritis being an example of a failure of his alarm reaction (a suggestion made probable by the great variety of traumata which may apparently initiate the disease), it occurred to me that it would be worth while to determine whether these substances were present in the blood of patients suffering from rheumatoid arthritis. I therefore supplied Dr. Ungar with six specimens of blood from patients suffering from various disorders unknown to him. He reported a complete absence of splenin A and the presence of splenin B in the 2 patients mentioned above who were afterwards treated with corticotrophin. After corticotrophic therapy, splenin B disappeared from the blood and splenin A was found. The other four bloods contained normal amounts of splenin A and no splenin B.

Ungar has since reported the presence of splenin B in the blood of patients with scurvy, various hæmorrhagic conditions, acute rheumatism and thyroid deficiency. Miss Vaughan-Morgan, who was taught the technique by Dr. Ungar, working under my direction at the Royal Northern Hospital, has found it in some cases of thyrotoxicosis.

Ungar and I then proceeded to look for splenin A and B in the blood of a number of patients suffering from active rheumatoid arthritis, some of them under my care and some under that of Dr. Harry Coke.

Since Dr. Ungar left for Canada, his work has been carried on by Miss Vaughan-Morgan at the Royal Northern Hospital. Since the results reported to me by Dr. Ungar and by Miss Vaughan-Morgan are not entirely in agreement, I review their results in separate tables. I have omitted actual figures of units of splenin A and B, because, though Ungar considered his test to be quantitative as well as qualitative, Miss Vaughan-Morgan and I came early to the conclusion that the test in our hands had only a qualitative significance.

(1) Tests Performed by Dr. G. Ungar on Patients Examined Clinically by R. G. or by Dr. Coke

Diagnosis	Number of cases	Splenin A Present	Splenin A Absent	Splenin B Present	Splenin B Absent
Healthy control	1	1	0	0	1
Rheumatoid arthritis, active	10	2	8	8	2
Rheumatoid arthritis, inactive	3	3	0	0	3
Spondylitis, active	1	0	1	1	0
Spondylitis, inactive	1	0	1	0	1
Non-articular rheumatism	9	3	6	3	6
Osteo-arthritis	1	0	1	0	1
Prolapsed disc	1	1	0	0	1
Active infective arthritis	1	1	0	0	1

Ungar (1947) has reported that in 12 healthy persons splenin A was constantly present and splenin B constantly absent. Bergel (1947) (personal communication) states that in 33 normal controls, splenin A was constantly present and B absent. Miss Vaughan-Morgan has recently embarked on a series of tests of healthy persons as a further confirmation.

(2) Tests Performed by Miss Vaughan-Morgan on Patients Examined by R. G. Before Treatment

Diagnosis	Number of cases	Splenin A Present	Splenin A Absent	Splenin B Present	Splenin B Absent
Rheumatoid arthritis, active	15	3	12	15	0
Thyrotoxicosis, before operation	9	4	5	6	3

In 3 cases tested also after operation, A was absent before and after, and B was increased.

Combining the series it is seen that of 25 cases of clinically active rheumatoid arthritis, splenin B was present in the blood of all but 2. Splenin A was present also in that of 5 only. The blood of 3 cases of inactive rheumatoid arthritis contained splenin A but no splenin B.

No conclusions can be drawn from the results in other disorders, but Ungar, Vaughan-Morgan and Bergel all found A present in and B absent from the blood of all healthy controls.

In the blood of the 2 patients with rheumatoid arthritis treated with corticotrophin, splenin A was absent and splenin B present before treatment; but splenin A present and B absent afterwards. The results were less clear-cut in the patients treated with procaine.

Dividing the cases as before, according to total dosage received, the following results were recorded:

Case No.	Dose	Splenin A Before	Splenin A After	Splenin B Before	Splenin B After	Result
I	10 grm.	+	−	+	+	No improvement
II		−	−	+	−	Moderate improvement
III		−	−	+	+	No improvement
IV	10 to 20 grm.	——Results of tests lost——				Great improvement
V		+		+		Great improvement
VI		+	+	+	−	Moderate improvement
VII		−	−	+	+	No improvement
VIII	Over 20 grm.	−	+	+	−	Slight improvement
IX		Tests not performed				Great improvement
X		−	+	+	−	Great improvement
XI		Tests not performed				Moderate improvement
XII		−	+	+	−	Moderate improvement

From this it will be seen that the 3 cases of rheumatoid arthritis which failed to improve all showed splenin B in the blood before and after treatment. In these 3 splenin A either disappeared or was never present.

Of those 9 cases which improved, all those tested showed the disappearance of splenin B during treatment and in 3 cases the reappearance of splenin A, previously absent.

Discussion

I fully realize that these findings are incomplete. My excuse for their premature publication is my belief that the time has come for all those who have in their possession any information which may possibly be relevant to the issue to place it at the disposal of workers on the subject of the endocrine aspects of rheumatoid arthritis. Only one definite fact emerges—that the blood of patients with rheumatoid arthritis usually contains a substance which increases the bleeding time of guinea-pigs and that this substance is usually absent after the treatment of the patients with corticotrophin or with large intravenous doses of procaine.

If Ungar's work on the spleen can be confirmed, my results afford a prima facie case for further work on the part which may be played by the spleen in the ætiology of rheumatoid arthritis.

Dr. Max Reiss : As far as I am aware, Hemphill and Reiss were in 1942 the first to treat patients with biologically standardized and purified adrenocorticotrophic hormone. The patients were a group suffering from involutional melancholia. Apart from the mental improvement a skin phenomenon was described which might be of interest for this meeting. " In every case the skin soon began to look and feel to the touch more supple and thicker . . . the hair of the head regained its lustre, losing some of its dry brittle quality." Later we saw that the skin became more elastic and its electrical conductivity decreased. Excretion of 17-ketosteroids was shown to be increased. We used only a dose equivalent to 1·5 – 3 mg. of one of the present American preparations. Their dose is many times higher than the hormone produced physiologically. The pharmacological action of such doses, apart from the beneficial effects as in rheumatism, can produce diabetic changes, alterations in the blood pressure and so on. These high doses will ultimately be used, as Thorn and his co-workers suggest, to test the reaction capacity of a patient's adrenal cortex only. Physicians dealing with rheumatism will have an opportunity to study biochemical changes involved in the rheumatic symptom complex. But therapeutic measures will be designed to increase endogenous production of corticotrophic hormone.

Dr. M. G. Good: I am very sorry to pour cold water on the hopes raised by the speaker; in the official report of the New York Congress, Hench *et al.* claimed no cure, not even a treatment but an investigation into a treatment of rheumatoid arthritis. The evidence available to date on a relatively small number of cases treated for a short time shows that daily injection of 100 mg. of Cortisone relieves the pain completely and thus enables movement in the diseased joints. However, this is due to a *temporary* relief of pain, and after cessation of the injection the patient is as bad as before, including a raised E.S.R. Hench himself called Cortisone "dynamite", which obviously cannot be given for months and years.

The hypothesis that a deficiency of Cortisone is *the* cause of rheumatoid arthritis is at variance with clinical observations. In Addison's disease no rheumatoid arthritis or rheumatism have been observed !

On the other hand it is necessary to point out the very close chemical relation between the structural formulas of Cortisone and other potent natural hormones, like sexual hormones and D-vitamin. Daily injections of enormous and unphysiological doses of Cortisone must needs produce unpleasant side-effects such as virilism in women, painful gynæcomastia in men. Among others the danger of malignant new growths cannot be excluded at present.

In contrast to the "dynamite" Cortisone I have been obtaining in the last twelve months excellent therapeutic results—I might even say a cure in rheumatoid arthritis (about 80–90 cases) by injection of procaine into specific "myalgic spots". [The cases were demonstrated at the meeting of the Clinical Section on October 14, 1949.]

Dr. Francis Bach : Compound E or Cortisone is not, in my opinion, and never will be, the treatment for rheumatoid arthritis. It is interesting to consider how, in the last twenty years, we who are interested in the study of rheumatism have seen, and even taken part in, the early phase of "focal infection", then that of focal conflict (psychosomatic studies) and now have returned to Sydenham's holistic approach.

The fundamental and dramatic work of Kendall, Hench and Thorn which we saw in America has advanced our understanding of man's endocrine system, and, in particular, the mechanism of the hypothalamic, anterior pituitary adrenotrophic, thyrotrophic, gonadotrophic splenic relationship.

I would mention two points of possible interest in this connexion. In those rheumatic patients to whom Dr. Greene referred who, some years ago, at my instigation, had their spleens removed, the disease has remained clinically "inactive". In one patient in whom the clinical picture was first that of an acute thyrotoxicosis, apparently with a normal basal metabolic rate, thyroidectomy was performed. This was followed immediately by the onset of an acute rheumatoid type of arthritis, with swelling of the joints and gross muscle spasm. There was no response to any of the orthodox methods of treatment. Then, some five years ago, splenectomy was performed and complete relief of muscle spasm and the disappearance of all clinical and laboratory signs of activity followed. Now the patient is undergoing a series of operations for joint reconstruction by Mr. Timbrell Fisher, the orthopædic surgeon.

Certainly we have much to learn about the adrenal, thyroid and spleen in their relationship to rheumatoid arthritis.

Dr. M. H. Lessof: Could Dr. Greene say how hepatitis is thought to cause remissions in cases of rheumatoid arthritis? Is there an analogy with cirrhosis or other liver disease, in which the liver's failure to destroy hormones may cause gynæcomastia (Davies, J. N. P. (1949) *Brit. Med. J.* (ii), 676) or fluid retention (Ralli, E. P., *et al.* (1945) *J. Clin. Invest.*, **24**, 316).

Dr. Raymond Greene: So far as I am aware there is no known explanation.

DISCUSSION: WHITHER ANTENATAL CARE?

Mr. Aleck Bourne described three phases in the history of the development of antenatal care, and paid tribute to the pioneer work of Pinard and Ballantyne.

He then proceeded as follows:

The fourth phase saw the gradual development of examination of the mother for the presentation, contracted pelvis, and prevention of toxæmia by repeated testing of the urine for albumin. For years these details absorbed the whole attention of the obstetrician, and in many clinics they are still the chief and even the only interest of those in charge.

At first the woman was asked to attend the clinic once or perhaps twice during the last weeks of pregnancy, because the emphasis was laid upon "structure", by which I mean the measurement of the pelvis and the size and presentation of the baby. Testing urine for albumin was the only example of the care of "function".

In these early days it was uncommon to examine the woman at the beginning of pregnancy, to consider her general health, personality and social surroundings. The almost exclusive attention to structure led us to interfere with pregnancy in the form of an enormous amount of surgical induction of labour and an ever-increasing practice of unnecessary Cæsarean section. We were obsessed by the risk of difficult labour due to contracted pelvis diagnosed by minor reductions of the external measurements. If, for any reason, the head was high and could not easily be pushed down through the brim, the woman was in danger of induction of labour. Herman, in his edition of 1910 of that truly remarkable book "Difficult Labour" actually gave a table correlating the length of the true conjugate diameter of the brim with the correct week for induction.

For each quarter of an inch reduction of the true conjugate he gave the correct date for induction of labour, beginning with the 28th week for a diameter of 2¾ inches. He admitted that the actual date should be confirmed by the possibility of pushing the head down because of variations of the size of the child, but he makes no mention of the importance of good uterine contractions.

Interference during the last month of pregnancy was practised on such a scale at Queen Charlotte's Hospital—and most others—that Watts Eden was able to publish a paper showing that the risk to the baby of premature delivery down to the 36th week was so small that induction could be performed without anxiety.

I have looked up the Queen Charlotte's Reports and find that the percentages of induction of premature labour of the total admissions were as follows:

	%		%
1908 —	2·3	1920 —	5·3
1910 —	4·0	1921 —	7·4
1912 —	2·5	1922 —	6·0
1913 —	5·0	1923 —	6·6

In the peak year of 1921 no less than one in every thirteen women admitted had their labour induced. In short, the consideration of labour up to very recent times was entirely mechanistic. There seemed to be no idea of the paramount part played by uterine function in meeting the minor difficulties due to certain abnormalities of structure.

During the years after 1930 the maternal death rate was still rising and there seemed to be little achievement as a result of fifteen and more years of antenatal care.

From 1928 the mortality had been steadily rising until it reached 4·41 per 1,000 live births, the highest figure since 1894. And this in spite of the better training of midwives and students, backed by publications from the Ministry, notably by Dame Janet Campbell. It is not surprising that critics appeared during the 1930s drawing attention to the disappointing

results and asking what was lacking in the whole system of antenatal care. It is necessary, however, to point out here that much of the mortality of mothers was not due only to failure of the purpose of antenatal care but in a large part to the mismanagement of labour. Though the standard of antenatal care may be very high, the woman may lose her life if she is savagely handled during labour.

One such article was published by Mr. A. J. Wrigley (*Brit. med. J.*, 1934, i, 891). He pointed out various defects, but the one which I wish to underline was the mechanistic approach to pregnancy and labour which led to so much unnecessary interference by induction of premature labour and Cæsarean section. Gradually it was realized that external measurements of the pelvis were useless, but the mechanists gained a further encouragement by the more exact estimation of the size and shape of the pelvis by X-ray pelvimetry. If the pelvic diameters could be measured to within half a centimetre and the diagnosis of gynæcoid, android and other shapes could be seen so clearly on the three main films it seemed that the prognosis of labour could be made with equal assurance. On radiological evidence alone many radiologists append an opinion on the prognosis of labour. If we have due regard for the part played by contraction and relaxation of the uterus in labour, we must realize that in the large group of minor deviations from what is arbitrarily recognized as the normal, it is clear that labour cannot be predicted unless we can also foresee something of function.

Throughout the whole range of medicine we are liable to restrict the normal state within too narrow limits. This was well described in a recently published lecture by Professor John Ryle. In obstetrics we are perhaps more guilty of these arbitrary standards than our colleagues. An outstanding example is the diagnosis of pelvic contraction by minor reductions of X-ray measurements. It is true that small reductions may be related to difficult labour if the uterine contractions are continuously feeble, but it is also probable that such a feebly acting uterus would find an equal difficulty if the pelvis were larger than the standard normal.

There are few complications of labour, even including placenta prævia, heart disease, eclampsia and many others, which do not lose something of their potential danger if the uterus acts strongly. If the pelvis is slightly contracted an efficient uterine function can flex and mould the head, dilate the cervix, rotate a posterior occiput, exert pressure on a low placental site, cut short the number of eclamptic fits, and overcome perineal resistance. In all these conditions the dangers are greatly reduced, indeed, labour will probably terminate without anxiety, but if on the other hand contractions are feeble and inconsequent, all these and other handicaps will involve both mother and child in peril.

It is unnecessary to define what is meant by good uterine function because all of us who have attended labour know well what it is. But if function is of paramount importance, can we, during the antenatal period, predict its quality or do anything to ensure it after labour begins? I think we can in most cases. Though speaking without anything like full knowledge of the physiology of the uterus in labour, I would claim that its action depends primarily on the personality of the woman, her emotional attitude to pregnancy and labour and the behaviour of her nearest relations. Secondly, it is dependent upon her clinical type. It is difficult to state briefly what I mean by these words. Let me illustrate. A gynæcoid woman has a characteristic physical shape, she has had a normal puberty and comfortable menstruation, and usually feels the well-known euphoria of pregnancy. She is seldom sick or complains of the common minor discomforts. Most of these women have a normal labour not only because of a normal structure but also because the uterus acts well throughout. Pain is minimal and the perineum dilates without serious tearing. Later the gynæcoid woman lactates well and quickly falls pregnant again. Though there are naturally exceptions, it is mostly true that if during the antenatal visits we can recognize a woman as clearly belonging to this type we can be satisfied that she will have good uterine function in labour. The opposite type is the android woman who lacks the characteristic figure and form of the first type. Her puberty may have been later than usual and often the menstruation has been painful, scanty and irregular. During pregnancy she is troubled with vomiting, vague pains in the abdomen, heartburn and many other minor discomforts. An occipito-posterior presentation is liable if she has an android pelvis, contractions are slow and feeble, there is much pain, with forceps delivery of varying difficulty and a chance of a deep perineal tear.

Uterine function can also be predicted by observation of the emotional attitude to labour, and this is as important as the recognition of the physical types. Many primigravidæ and also those who have endured the ordeal of a slow and difficult labour, with possibly a dead baby, begin their pregnancy in a state of ignorance, uncertainty and fear. Such women have had bad advice and often a mother-fixed childhood and adolescence. It is easy for a doctor with insight, sympathy and understanding to see through the shell of reserve and spurious courage. He can also predict that, should the state of fear persist unresolved, labour will be slow, painful, difficult and even hazardous.

The times of the antenatal visits give opportunities not only for the diagnosis of the physical type but also for an understanding of the woman's emotional state. We can do nothing to alter the physical type, but in both groups, especially the second in which fear is predominant, we can do much to prepare the mind and feeling by which fear can be exorcised and so uterine function liberated from the inhibition imposed by fear. After years of contact with pregnant women and labour I am firmly convinced that uterine function is closely related to the woman's mental outlook on childbearing. If a woman approaches and enters labour in a condition of uncertainty, lack of confidence, and therefore fear, the function of the uterus will be in disarray. Remembering that many of the minor handicaps of labour can be overcome by good uterine contractions, and also that the dangers of the more serious complications can be mitigated, I assert with conviction that the encouragement of function and less emphasis on structure will mark a new advance in the conduct of antenatal care. While I stress the importance, firstly of fear and failure in confidence, I would also suggest that all the other normal physiological processes should be remembered. So far there is no evidence that nutrition has any influence on actual uterine function though it is certainly a serious factor in the release of labour before its appointed term, with the delivery of feeble premature babies.

The diet of pregnant women in this country since 1939 has been a special care, and I think we owe to this something of the reduction in the number of stillbirths and neonatal deaths. It is indeed unusual to find a pregnant woman who is unmistakably undernourished in these days, though I do believe, perhaps wrongly, that they do not get enough protein. It is important, in my view, to encourage her to eat all the meat, fish, cheese, eggs and milk that she can find. Physical exercises during pregnancy have taken a place in antenatal care during the last few years in many hospital clinics. I am sure of the value of this form of prophylaxis, not only by reason of physical advantage but also because the woman feels that she is contributing something to preparation for labour and so gains a feeling of confidence in the value of her own positive efforts.

The tangible reality of such details as measurement, X-ray diagnosis, presentation and the other physical signs of the pregnant woman may satisfy our minds as we look for the grounds of prognosis, but the figures of the Registrar-General during the early 'thirties showed that this form of antenatal care was a failure. Whither, therefore, do we go from here? I repeat that we have not given enough attention to the part played in labour by uterine function. During pregnancy we can, by insight and experience, make a fair prediction of the probable course of labour, and by understanding, reassurance and confidence, do much to ensure that labour shall be easy and normal.

Professor W. C. W. Nixon: The half-century has almost turned since Ballantyne (1901) published his article—"A plea for a pre-maternity hospital"—containing the first suggestion of an antenatal clinic or hospital. During these fifty years opinion and practice have changed, in some instances swinging a full circle, so that it is time to reflect upon "whither" we are tending.

I can recall over a quarter of a century ago, when I was a student under Mr. Aleck Bourne, his plea for a shift of emphasis from structure to function, in relationship to the parturient woman. The mechanistic approach was in vogue at that time. It still exists in some places but there is in others an awakening to the importance of the holistic attitude towards the individual. The woman must be taken as a whole since her psyche and soma are so interwoven that neither can be neglected at that most critical time of her life, namely, pregnancy.

Mr. A. J. Wrigley stirred the complacency of the mid-thirties when he showed that antenatal care was failing. Meddlesome midwifery had shifted from the labour room to the antenatal department with results sometimes disastrous to both mother and baby, especially in the instance of induction of labour. Mr. Wrigley had as his senior colleague at St. Thomas's Hospital the late Dr. John Fairbairn, who was responsible for the introduction of the term "constructive hygiene" of pregnancy and who tried so hard to convert to this attitude those doctors and midwives who had charge of pregnant women.

These were the beginnings of the new attitude towards pregnancy. The cynicism of Mauriceau and his view of pregnancy being a disease of nine months' standing was no longer supportable. Unfortunately, in some quarters this emphasis on the abnormal rather than the normal still exists. The normal pregnancy and the normal delivery have not the drama of the abnormal, and the assistant, student or midwife gaining experience finds life dull when the week has passed without any untoward incident.

We are all aware of the importance of nutrition and it is in the antenatal clinic that so much can be taught in a practical way if a Food Advice Bureau is included in the service. In view of the prevalence of nutritional anæmia the hæmoglobin of every mother should be estimated at her first visit and again at the 36th week. The importance of adequate hæmoglobin has been confirmed by Wills and others (1947) who have shown the value of iron

therapy in maintaining a normal hæmoglobin level and thus reducing post-partum hæmorrhage.

For some years routine weighing of pregnant women has been the practice in some clinics. But is it really such a valuable aid in the early diagnosis of toxæmia? Ambrose Rogers, Lecturer in Mathematics at University College, and J. G. Dumoulin, Assistant in the Obstetric Unit, have analysed the weights of two groups of mothers during 1948 (Fig. 1).

Weight increases regarded as excessive by arbitrary standards A and B, in lb.:

Periods in weeks	1	2	3	4	5	6	7	8
Standard A	4	6	8	10	12	14	16	18
Standard B ..	3	5	6	8	9	11	12	14

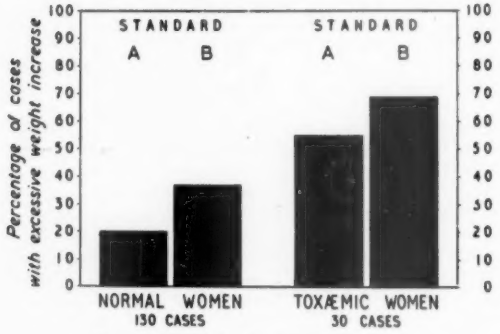

FIG. 1.—Weight in pregnancy.

This shows there is a tendency for toxæmic mothers to put on more weight than the mothers having normal pregnancies. But owing to the large standard deviation of the increase it is not much use as a diagnostic aid. It is often wrong to regard an excessive weight increase as indicative of toxæmia. We believe that the time spent on routine weighing could be better spent in giving advice about pregnancy.

During the past two years we have arranged that every mother should have a routine chest X-ray. Mr. T. Ealand, Assistant in the Obstetric Unit, has analysed the figures during this time (Table I).

TABLE I.—ROUTINE CHEST X-RAY EXAMINATION OF EXPECTANT MOTHERS, JANUARY 1946 TO AUGUST 1949, UNIVERSITY COLLEGE HOSPITAL

Total number of mothers examined		3,581
No. of cases of pulmonary tuberculosis discovered by X-ray examination ..		28 (0·74%)
Active	13	
Inactive	15	
Incidence of pulmonary tuberculosis in pregnancy, including those cases known to be infected before pregnancy..		2·61% (95 cases)

It will be seen that 28 cases (0·74%) of pulmonary tuberculosis were detected by this routine X-ray. All these cases had had the usual chest examination by the house surgeon and in only one were any abnormal signs discovered by this physical examination. I feel that routine chest X-ray of pregnant women should become obligatory.

Version.—To turn or not to turn? Mr. Dumoulin has shown from figures he has collected from 1947 and 1948 that there is a place for external cephalic version as a treatment for a breech presentation discovered in pregnancy. Version should be tried first without an anæsthetic; if it fails, then it should be tried again under anæsthesia.

These points are most important, as is the customary attention to the pelvis, the engaged head, the blood pressure, the urine and so forth.

But all this does not make up the whole picture. We cannot neglect the part that fear plays in the birth process. At University College Hospital we have found that one way of lessening this fear is by holding special classes for our mothers. Dr. Shila Ransom, anæsthetist to the Obstetric Unit, is responsible for their organization. In these classes, we find that simple explanations of the changes in pregnancy and of the birth process go a long way to increase confidence. As is well known, it was Dr. Dick Read who pointed out the importance of the pain-fear-tension syndrome. The physiotherapist at the special classes

teaches various types of breathing, posture and exercises. The exercises which we use are those elaborated by the late Mrs. Helen Heardman, who did so much to advance the idea and practice of natural childbirth.

Antenatal preparation along these lines, based directly upon the work of some of our compatriots, has been carried out with most successful results by Goodrich and Thoms (1948) of Yale University.

Mr. A. J. Wrigley: There are some aspects of prenatal care in which I have seen changes occur in the last twenty-five years, or in which I would have wished to have seen changes occur.

My first observation is that at long last there are signs that the general health of the patient deserves, and is getting, an ever-increasing attention. Clinics still exist today where one person examines all the specimens of urine, another rushes round with a manometer and finally the "Chief" goes from couch to couch performing an abdominal examination. The patient as an individual need not exist. I tell students to answer the following question: "Which would you prefer to take charge of in her confinement—a healthy woman with a malpresentation or an unfit woman with a normal presentation?" The answer is surely the former, and the moral is that in our prenatal care we must place more emphasis on the general health of the patient.

In late years sincere and energetic measures have been adopted to try to prepare the woman both physically and mentally for her first labour. The physical side is dealt with by instruction in, and supervision of, the performance of remedial exercises designed to tone up the muscular structure of the whole body, to educate especially the muscles of expulsion, to teach correct stance, and to teach the patient how to relax. The first assessments of this work are beginning to come in and so far the results are hardly encouraging. Dr. Helen Rodway published a careful review of the results of physiotherapy in pregnancy on some 340 women who were confined at the Thorpe Coombe Hospital, Walthamstow. A comparison was made between these patients and a similar number of controls. There was no statistical difference between the two series. In 1948 similar analysis was made on 140 women at St. Thomas's. The results were almost identical in the exercise and control groups and the conclusions reached agreed with those of Dr. Rodway. In a further attempt to help our patients we have at St. Thomas's, since the analysis of the group of cases just mentioned, combined physiotherapy with what I may term a mild form of psychotherapy. Successive groups of patients who elect to join the classes in physiotherapy attend what may be called "talks by Sister". In these talks an attempt is made in the simplest language to explain the physiology and management of labour and the patients are taken to see the wards and nurseries. We have made a similar analysis of the results in some 106 women who have been delivered after going through the combined course. The results are identical with a similar number of controls. I have no doubt that prenatal education or treatment, call it what you like, on these lines is in its infancy and that the crest of its wave will not be reached for some years to come. Nevertheless, I venture to suggest, and to put on record, that the results will fall far short of expectations and give rise to great and widespread disappointment.

I now turn to three minor points. I first wish to refer to the performance of external cephalic version of a breech presentation in pregnancy. A great deal of consideration has been given to this successful piece of prophylactic medicine. We have appreciated that the cause of the malpresentation is at any rate worth a thought, that often no cause exists other than that the fœtus is premature, that in consequence version is often unnecessary before the 34th to 36th week of pregnancy, that its performance is fully justified by the advantages likely to accrue to the baby and mother, and lastly that in its performance, especially if the patient is anæsthetized, no great force should be used. If these conditions are observed, and if a sensible anæsthetic is used, I believe this item in prenatal care will in the future confer still greater benefits.

Next I hope that in the years to come much unnecessary anxiety, and discomfort from pointless and ineffective medical inductions of labour, will be avoided by a more common-sense outlook to what we term the "expected date of delivery". Let us realize that, at the moment at any rate, we are not all made alike, and that whereas most women will mature a fœtus of normal weight in a pregnancy lasting about 40 weeks, there are many exceptions both in the weight of a fœtus that is mature and in the length of time necessary to bring it to this state. Therefore we meet constantly women who will bring to a state of maturity a

big baby, or a normal baby, or a small baby, in a pregnancy of under 40 weeks' duration, or of 40 weeks' duration, or of over 40 weeks' duration.

Next I wish to suggest that in the future less, and not more, attention is given to the prenatal preparation of the patient for breast feeding. Other than a cursory observation that the breast anatomy appears reasonably normal, and a casual observation that I suppose there is no doubt that the woman accepts breast feeding as the natural thing to do, I advocate that nothing be done with patients under my care. I regard as unnecessary, and indeed undesirable, all treatment of the skin with either spirits or ointments and all massage of the breasts. The prenatal use of expression and nipple shields as advised by Dr. H. K. Waller would appear to be most successful in hospital practice where a routine in breast feeding is necessary.

X-ray examination of the bony pelvis and X-ray pelvimetry.—The possible disadvantages and dangers of this method are well known, but as the result of years of painstaking observations by workers such as Rohan Williams, Chassar Moir and others in this country our knowledge has increased enormously. The technique of radiography has improved, the risks of misinterpretation of the films have decreased, and the undoubted assistance of X-rays to a clinical examination has been demonstrated. An X-ray examination should be made of the pelvis of every woman embarking on her first pregnancy, and the results interpreted by a skilled worker.

I have left to the last the point I consider the most important. Indeed, I believe its importance to be such that unless a complete change of policy is accomplished, all our efforts to improve upon our clinical work are wasted and are set at nought. It is necessary for me briefly to refer to what I may term the evolution of our antenatal work up to July 5, 1948.

In the early 1920s a tremendous fillip was given to the efforts of the teaching schools by the appreciation of the value of prenatal care by the public health authorities. Their efforts resulted in the establishment of clinics all over the country. Numbers were all that mattered, and indeed it would appear that more credit was to be gained by the number of attendances made at such clinics than by any other criterion. Little or no attempt was made seriously to assess the value of the work—it was assumed that the value was immense—almost sacrosanct in fact: it appeared not to matter who took the clinic as long as the man or woman in charge was a registered medical practitioner. A most pernicious system was quickly established whereby the antenatal officer was completely detached from the subsequent events of the confinement. I know what I am talking about because I have suffered at both ends of this string. For some years I worked as Antenatal Officer to a large borough. Similarly, and for many more years, I have worked at what may be termed the recipient end. At times I would have been frankly amazed at what can only have been the attitude of complete indifference on the part of the medical officer in charge of a borough clinic had I not experienced myself the sense of detachment and frustration inherent in the conduct of antenatal clinics that were utterly divorced from the bedside and lying-in wards. I would here note that I am fully appreciative of the benefits conferred on the patients by the establishment of numerous antenatal clinics throughout the country. They save travelling, and their most important social workers establish a local knowledge and liaison. But this does not mean that the medical officers must be divorced from their colleagues working under the Regional Boards or Teaching Hospitals.

When, a few years ago, it became certain that a National Health Service was to be established, many of us were sure that this arrangement would be abolished. Alas, the state of affairs now is worse than it was five years ago. The gap between the Local Authority antenatal care and the Regional Board confinement is greater than ever. Before 1948 this arrangement could at least claim that its inception was entirely fortuitous, but under the National Health Service the splitting of the care of the pregnant woman has been deliberately planned. Such planning can never have been in the interests of National Health. I have dwelt on this subject at some length for I believe that as long as the present system obtains and the care of the woman in her pregnancy and confinement remains divided we are largely wasting our time in the consideration of other and clinical details.

Mr. Arnold Walker said that he objected to Mr. Wrigley's condemnation of Local Authority antenatal clinics. While no one has claimed that the separation of antenatal from intranatal care is satisfactory, it must be remembered that this service was developed because it was the only way in which the great majority of pregnant women could get reasonable supervision during their pregnancy and the best way in which the social and educational aspects of antenatal care could be provided. Those who have staffed these clinics in the past have done excellent work and there is a real place for them in the future. Mr. Wrigley also condemned "routine" visits to the clinics. Surely the detection of early toxæmia is almost

entirely a matter of routine, requiring office organization and a follow-up system. Antenatal services must be brought to the patient and her visits must be made easy and attractive. The examinations at the clinic are almost entirely a matter of routine but her visits provide an ideal opportunity for educating her in the tasks that lie ahead. What is needed is not the abolition of the local clinics but their proper correlation with the hospital, the general practitioner and the midwife.

With regard to antenatal exercises, he was sceptical about their value and considered that before much money and effort are expended on this refinement of antenatal care, its value should be proved by a scientific analysis of the results obtained by selected clinics.

Dr. C. V. Pink said that antenatal care should begin as soon as a baby girl is born for the attitude of the mother to childbirth certainly gets across to her children and we did not know how early in life the influence would act.

In Stonefield Maternity Home, the work had been developed on lines very similar to those described by Professor Nixon. The results have been very obvious in more quick labours, less shock and hæmorrhage, less need for inhaled anæsthetic and a forceps rate reduced to 3·4%. But much more important—the elimination of fear permits a woman to become intensely happy in the birth and to appreciate its deep significance as one of the major events of her life.

Dr. Pink was not surprised to hear that statistics show no reduction of hæmorrhage, &c., in units where "exercises" have been introduced; for success a fully integrated team of obstetrician, physiotherapist, and labour-ward nursing staff is necessary. He was just old enough to have seen the difference in midwifery when the antenatal clinics were organized in London about twenty-five years ago. He believed the development Professor Nixon had described constituted a step forward of equal magnitude and that the next generation would so appraise it.

Dr. John Burton: The present system of antenatal care involving Local Authority, general practitioner and hospital antenatal clinics inevitably led to some interruption of continuity of care, but this might equally well happen within any hospital. One of the main values of antenatal clinics was the education of women for motherhood when their interest is centred on this subject. In this field, the Local Authority clinics and certain hospitals are well equipped and progressive. It was unlikely that general practitioners would ever have the time to carry out such work.

This education of the mother should be attacked by all methods, physical and emotional, through exercise, talks and discussions and this work should be done by the antenatal team of midwife, health visitor and if necessary, physiotherapist.

In order to co-ordinate this service with general practitioner midwifery, health centres as envisaged by the Act are essential.

Miss Margaret Smith speaking as a physiotherapist said that there were two points of particular interest to her, namely, function as stressed by Mr. Bourne and relaxation, by Professor Nixon.

Physiotherapists had a special interest in *function* and felt that it was their particular job to help to improve function wherever possible. It was, therefore, one of the chief aims of the physiotherapist in antenatal training.

With reference to relaxation, she had found that patients much appreciated help in learning how to relax. They were encouraged to relax for a short time during the day as well as to relax the whole body on going to bed. Patients reported that they were able to sleep much better and that they suffered less from fatigue during the day.

Dr. Elizabeth Tylden asked for a closer collaboration between obstetrician and psychiatrist.

In reviewing 50 cases of mental upset during pregnancy and the puerperium certain things became apparent. First these disorders are an expression of the previous personality and experience of the individual woman. Second, they all have one thread running through them. They are an exaggeration of the general psychological change which always occurs during these times: a change which is generally recognized, but is difficult to define.

She asked for a more early recognition and treatment of the precursors of puerperal insanity. She would ask the meeting to take very seriously, and treat psychologically, the woman who is more sleepless than the average, the woman who is more afraid than the average of childbirth and the woman who shows a pathological aversion to, and loathing of the natural process of breast feeding. The causes for all these symptoms lie far in the past, as well as in the present situation.

The answer to many of the problems mentioned lay in a combination of the two agencies discussed by Mr. Arnold Walker and Professor Nixon. On the one hand, "individual psychotherapy" as one might say; the careful attention of one person who inquires intimately into the patient's whole past and present states. On the other hand, the classes and group instruction of U.C.H. represented "group psychotherapy", the acquisition of necessary information and sharing of it with others which can make the patient aware before delivery that others are going through the same experiences as herself.

The Americans have made several attempts to team together the obstetrician and the psychiatrist, and have discovered certain things. Mainly the immense influence of apparently minor ill-calculated remarks in precipitating a major crisis. She would like to see disappear the attitude in some midwives that a woman because she is in labour becomes mentally deficient. Praise and blame have no place in the proper conduct of labour. Too often the precipitating cause of breakdown has been a sense of shame at failing to breast-feed after repeated exhortations, or a feeling of shame at reacting to pain, induced by the scoldings of one who has not personally experienced that pain but exhorts the patient to pull herself together. Such exhortations must be replaced by an understanding of why particular sorts of behaviour occur.

Dr. A. J. Martin felt that too much accent was placed on the actual anatomical side of labour and on the incidence of abnormal conditions in regard to the evaluation of antenatal teaching. He found that in the women attending antenatal classes at the Royal Free Hospital there had been a marked reduction in the incidence of backache and that many stated that they felt "better in themselves", even when attending after the day's work. He felt that a great deal of the value of classes on Mrs. Heardman's lines was the removal of fear of the unknown.

Dr. Martin said that there was a difference between the antenatal training as advocated by Sister Randall and that of Mrs. Heardman, the former being largely concerned with position and labour, with the accent on exercises, while Mrs. Heardman's technique was largely concerned with relaxation, correct breathing and general education in the physiology of pregnancy, with the idea of removing the normal woman's nervousness.

Dr. Edward Cope said that much emphasis had been placed upon the importance of antenatal exercises, particularly those suggested by Grantly Dick Read and taught at University College Hospital and elsewhere by the late Mrs. Heardman, which purport to promote muscular relaxation, and allow an easy and smooth delivery.

Some years ago Mrs. Heardman organized antenatal classes at the Leeds Maternity Hospital and, in addition, a twenty-four-hour service was instituted for the continuance of treatment during labour. During two years' residence at this hospital, he was able to form some impression of this work. There appeared to be no reduction in mortality and morbidity of patients treated in this way.

Professor A. M. Claye in a lecture delivered at the R.C.O.G. states that he has seen no figures which confirm the view expressed by Dr. Grantly Dick Read, that the incidence of lacerations of the soft parts and of post-partum hæmorrhages are reduced. He analysed the records of 100 recent primigravidæ who had attended the classes and of 100 controls and there was no significant difference in the figures for perineal tears, cervical tears and episiotomies. His opinion is that the benefit is mental rather than muscular.

Many speakers had preferred to keep the discussion on a high plane and avoid mere statistics. However, one had always understood that the success or failure of antenatal care could best be assessed in terms of maternal and fœtal mortality and morbidity. Mr. Aleck Bourne deplored the high incidence of surgical inductions in past years and quoted 6% as a peak figure. In this connexion he would like to quote induction figures from the Churchill Hospital, Oxford. This was a new unit under the directorship of Mr. John Stallworthy.

In 1948 there were 752 deliveries, an induction rate of 7%, a stillbirth-rate of 16 per 1,000 deliveries and a neonatal death-rate of 10·6 per 1,000 deliveries.

In 1949 (up till October 18) there were 762 deliveries with an induction rate of 16%, a stillbirth-rate of 5 per 1,000 deliveries, and a neonatal death-rate of 14·6. The Cæsarean section rate of the whole series was 0·8% and the forceps rate 6·92%. There had been no maternal deaths.

There were no inductions for disproportion, the majority being for pre-eclampsia and postmaturity. It will be seen that despite the increase in surgical inductions there has been a 25% reduction of fœtal wastage, and of the four stillbirths in 1949 at least two could have been saved by earlier induction.

DISCUSSION: THE INTEGRATION OF PREVENTIVE HEALTH SERVICES. [*Abridged*]

Dr. A. T. Elder, *Deputy Chief Medical Officer, Ministry of Health and Local Government, Northern Ireland.*

Of recent years few words have been bandied about in official language with such frequency and so little effect as the word "Integration". The Concise Oxford Dictionary defines the verb as meaning "to complete (imperfect thing) by the addition of parts or to combine (parts) into a whole". Chamber's Twentieth Century Dictionary introduces the meaning "to renew", and this is supported by several other dictionaries. Whether we accept these meanings or appeal to the Latin origin, we are forced to the logical conclusion that if a need for integration of something exists then that something is at present incomplete or "requiring to be renewed".

We in Northern Ireland have adopted a way of life in our Preventive Health Services differing in some measure from that followed in Great Britain. I shall describe in simple terms only those ideas which we have adopted in the past few years as making for this sense of completion or renewal of vigour of which I have spoken, and to explain what merit we think lies in them. When we consider the relative size of populations involved, it becomes clear that what may produce a fair measure of success in a smaller population may not be equally applicable to the larger. Nevertheless the lessons to be studied are in large measure the same. I will deal with but some of the major ideas we have adopted, though this does not by any means cover the field of endeavour.

The transfer of School Medical Services.—When the Public Health and Local Government (Administrative Provisions) Act (Northern Ireland), 1946, established the functions of the new Health Authorities with their Statutory Health Committees, provision was incorporated in the Act for the transfer by means of Statutory Instrument of the central control of the health of school children from the Ministry of Education to the Ministry of Health and Local Government at an appropriate time and with the consent of the former Ministry.

Four sections only were transferred, and in such sections for *Education Ministry* we now read *Health Ministry*, and for executive purposes for *Education Authorities* we read *Health Authorities*. The sections involved were those dealing with: (*a*) the ascertainment of physically handicapped children, from whatever cause the disability might arise, and this ascertainment to be lawful amongst children from age 2 years upwards; (*b*) the provision of medical inspection and treatment—this to include the voluntary and grammar type of school; (*c*) the power to ensure cleanliness amongst school children, including the control of vermin infestation; and lastly (*d*) the ascertainment of children considered to be ineducable due to disability of mind.

Subsequent to the Appointed Day the Ministry of Health produced its School Medical Regulations based on these four sections of the Education Act. The School Medical and Dental Records approved in England were adapted for use in Northern Ireland and issued through His Majesty's Stationery Office to the Health Committees. Provision was made for research within the framework of the School Health Service, as is the case in the Scottish Regulations, and in addition the School Health Record

Cards are made available on request, and by Statute, on the individual ceasing to be a pupil at school-leaving age, to recognized medical attendants who may be: (*a*) the family practitioner; (*b*) a medical officer employed by the Northern Ireland Hospitals Authority or the Tuberculosis Authority; (*c*) an Examining Surgeon (factory M.O. under the new Act) under the Northern Ireland Factories Act, 1938; or (*d*) a Medical Officer to any University or other educational establishment.

Dental records are made available to dental practitioners under contract to the Northern Ireland General Health Services Board.

Health propaganda having been laid as a duty upon Health Authorities by the Health Services Act of 1948, health education in schools again now falls to the Health Authorities.

As to the officers necessary to the adequate prosecution of this service a loophole had been made in the previously mentioned "Administrative Provisions" Act for the appointment by each Health Committee of such additional officers as might become necessary for the efficient carrying out of the functions of the Committee. Under this section the Divisional County Medical Officer of Health becomes also the Area School Medical Officer, the Health Visitor becomes the School Nurse, the Sanitary Officer ascertains the hygiene and sanitary condition of schools, and so on, and a similar practice obtains in the County Boroughs.

It may be asked why only four sections of the Education Act were transferred.

It was considered wise to leave the administration of the School Meals and Milk Service with the Education Authorities, because of its close association with the everyday school life of the child, and the special interest of the teaching profession.

The health aspect of this catering service, organized as it is through the medium of catering advisers, is amply dealt with by way of an advisory service for the Medical Officer of Health in regard to the nutritional aspects of school meals and the preventive measures necessary to the hygienic control of school canteen food preparation.

The safety of school milk was provided for by means of Regulations passed by the Ministry of Education under which all milk supplies to schools are subject to the approval of the appropriate Medical Officer of Health, and may be stopped because of an outbreak of disease or uncleanliness on his authority alone. He takes action and subsequently notifies the appropriate Ministry, in this case the Ministry of Agriculture in Northern Ireland.

Executive action in regard to the remedying of hygienic defects in schools is vested in the School Managers, in many instances this means the Ministry of Education, and is enforceable by the local sanitary authority under the Public Health Acts. It will be noted that the initiative in this action comes, in the first place, from the Ascertainment Officers of the Health Committees, that is, the School Medical Officer and his Sanitary Officer.

The provision of nursery classes and schools remains with the Education Committees and the ordinary School Personal Health Service applies here.

Having ascertained the numbers of pupils who are suffering from physical handicaps the Health Committee makes representations to its appropriate Education Committee in regard to the schooling appropriate to each type of child ascertained, and the provision of such special schools as may be necessary remains with the Education Committees. Where such provision for reasons of economy clearly involves the areas of several Committees, and indeed for some disabilities, the entire Province, consultation takes place at Ministerial level between "Health" and "Education" in the first instance. At health authority level close liaison exists between Medical Officers of Health and Directors of Education, and the Medical Officer of Health may attend education authority meetings as occasion may demand.

The scheme thus outlined has been expanding and developing over the past two years and so far has proved to be a very happy and efficient service. Of the elementary

school population 98% are in receipt of free milk supplies (95% of this is pasteurized milk). If the School Meals Service is not as far advanced as this it is not due to lack of energy on the part of Directors of Education, but rather on account of lack of building materials and kitchen equipment.

The Northern Ireland Tuberculosis Authority.—Prior to 1948 the care of tuberculous persons had been vested in the local authorities as is the case in Great Britain. The Tuberculosis Act (Northern Ireland), 1947, created a new autonomous authority called the Northern Ireland Tuberculosis Authority in which now rests the control of tuberculosis in all its aspects, the prevention, as well as clinical treatment, of tuberculosis. The Authority has representatives from the Health Authorities, and for administrative purposes the day-to-day organization is centred on a director who is a medical man, a deputy director, and a lay secretary.

The Province is divided into five dispensary areas, and each of these, together with the sanatoria of the area, is under the control of a tuberculosis officer and appropriate medical staff. Notifications of disease are sent to the area tuberculosis officer by the general practitioners, who, by regulation, notify not only proven but suspected tuberculosis. The operation of mass miniature radiography is vested in the Authority as is the B.C.G. vaccine service, and all matters relating to tuberculosis research. The Authority possesses its own research laboratory.

Necessary links have been established with the Medical Officers of Health and the Hospitals Authority. The appointment of specialists, such as thoracic surgeons, rests with the Northern Ireland Hospitals Authority in consultation with the Tuberculosis Authority.

The Tuberculosis Authority employs its own After-Care Officers who are duly qualified Health Visitors, but the home nursing of tuberculosis cases is catered for, in order to avoid duplication, by the Home Nursing Service of the Health Authority. This is a much simpler process than it sounds because all that is required is a written request for the services of a nurse to the appropriate Medical Officer of Health.

Compulsory vaccination.—The law in Northern Ireland is regulated principally by the Vaccination (Ireland) Act, 1863, and the Vaccination (Ireland) (Amendment) Act, 1879, and vaccination against smallpox remains compulsory to this day.

The percentage of vaccination related to total births registered was not 100% as might be inferred but was as follows:

1943, 69%; 1944, 70%; 1945, 80%; 1946, 76%.

The factor of importance in the operation of compulsory vaccination was that the "Conscience Clause" was never introduced in the Northern Ireland legislation. Occasional prosecutions for non-compliance with the law were usually followed by a spate of vaccinations.

During the past twenty years, during which period about half a million primary vaccinations would be carried out, only one confirmed case of encephalitis following vaccination, has come to official notice, and in this case the patient had been vaccinated with lymph which did not come from the usual source of supply.

Central Government medical and ancillary staffing.—The medical, dental, nursing, and sanitary staff of the Government is wholly employed by the Ministry of Health and Local Government. No other Ministry, such as Education, Labour, Commerce, Home Affairs, Finance, or Agriculture, possesses any medical and allied staff, and the Ministry of Labour is also the Ministry of National Insurance. As regards selection of staff to operate under the Chief Medical Officer, while each one may deal with a certain amount of general medical work, each has also some branch of the Government service in which he or she specializes. Thus, advice is afforded to other Ministries by the Health Ministry through administrative channels on matters of policy or where no urgency exists, and for routine inspections or urgent medical advice direct access to the professional officer concerned is readily possible.

Items are dealt with, therefore, under subject matter rather than by choice of individual, and no officer is seconded to another Ministry. For example, matters relating to epidemiology and hygiene will be advised upon by the Senior Medical Officer of that section, whether raised by the Ministry of Health, Agriculture (e.g. milk production) or Commerce (e.g. cafés, restaurants, &c., under Tourist Traffic Board). Again, child health whether in regard to Ministry of Health matters (Infant Welfare Clinics), Education (School Health), or Home Affairs (Deprived Children and Approved Schools) will be the concern of the Senior Medical Officer for Child Health.

A Senior Medical Officer for Mental Health advises on the mental health of school children, children in the care of homes and societies or approved schools, and also on those referable to the Hospitals Authority as ineducable in the ordinary way. He also performs the functions applicable to the former Board of Control and as Inspector of Mental Hospitals.

The Medical Referee Service comes directly under Ministry of Health and Local Government control.

The Chief Medical Officer is also Chief Medical Officer to the Ministry of Labour and National Insurance, Chief Medical Inspector of Prisons, and Chief Medical Adviser to the Ministry of Finance on Civil Service health.

An advisory link has been established with the Chair of Social and Preventive Medicine at Queen's University, Belfast, for matters of abstruse professional interest or research.

Industrial health.—A Medical Officer specially versed in industrial hazards is employed, with some part-time assistance, to act as a Referee under the Industrial Injuries Act, and to supervise the work of the Medical Boards. A warrant as Inspector of Factories was issued to him two years ago, but in addition warrants are also held by the Senior Medical Officer for Hygiene and Epidemiology, and the Chief Medical Officer and his Deputy. Thus the forms for inspection and matters of general policy have been advised upon, medically speaking, administratively, clinically, and from the public health point of view.

With regard to legislation, the Factories Act (Northern Ireland), 1949, provides for the substitution of a general practitioner by an officer of a Health Authority to the post of Examining Surgeon, with the approval of the Ministry of Labour when such a post becomes temporarily vacant, and also for the appointment of works doctors as Factory Medical Officers.

The sanitary aspects of all factories are controlled by the Health Authorities, and as far as factories not using power-driven plant are concerned all matters in relation to public health conditions of work are controlled by them.

Study of the relative number of actual hazards compared with the general hygienic conditions requiring survey in Northern Ireland shows that it might be rational to employ a hygiene-trained Medical Officer for the routine inspection of factories, with reference, where desirable, on matters of special hazard to the Medical Specialist Officer in Industrial Diseases.

After a brief reference to the General Health Services Board and Mental Health Service, Dr. Elder concluded by saying that it was for his hearers to judge whether the picture thus presented constituted a fair measure of integration in the real sense of the term. A tremendous amount of goodwill on the part of all Ministries was necessary, and financial considerations naturally played a large part in the determination of the pattern.

Dr. Dennis Geffen: Now that we have had over a year's experience of the National Health Service Act we should ask ourselves whether we have secured adequate integration of the Health Services.

The midwifery service.—The local health authorities are responsible for domiciliary midwifery. They may either employ the midwives themselves or they may contract with voluntary organizations or hospital management committees to provide the service for them. The hospital management committees must make provision for hospital confinements.

For domiciliary midwifery to be satisfactory there is need of a midwife and possibly a doctor, a flying squad associated with the obstetric department of a hospital, and hospital beds, both ante-natal and midwifery. I cannot see that there is any sense in leaving domiciliary midwifery with the local health authority with power to hand it back to the hospital management committee. It looks to me as if midwifery, both hospital and domiciliary, ought to be in the hands of the hospital management committees, who should also supervise the work of the domiciliary midwife.

Again, there seems to be some confusion between the domiciliary midwife, the general practitioner obstetrician and the doctor who may be called out at the wish of the midwife acting as such, and who will then be paid by the local health authority. At the present moment the general practitioner gets £5 5s. for making an ante-natal and post-natal visit and attending the confinement if required. For a general practitioner obstetrician the fee is 7 guineas. On the other hand, if a midwife acting as such should call in a doctor, he may be paid £4 14s. 6d. for an operative emergency, as for example the removal of a retained placenta, £2 12s. 6d. for a single visit during labour, or 3 guineas for suturing the perineum or resuscitating a baby, or for one visit during the daytime, 10s. 6d. All this seems nonsensical to me. It cannot be right to tell a doctor that, having received 7 guineas, there is no need for him to attend the confinement unless so requested. I should have thought that a better integrated service would have been the provision of a midwife under the scheme, with power to call out a doctor if necessary. It would be better still if the domiciliary midwifery service were provided by the hospital management committee, who would then back up its own midwives working on the district with the provision of medical assistance, a flying squad, second opinion, assistants and so on, through the wholetime hospital obstetric staff. If it be argued that normal confinements should be conducted by a midwife, then this should be the provision made by the National Health Service Act, and if a doctor is considered unnecessary or a luxury, his services as a domiciliary obstetrician should be outside the scope of the Act.

Maternity and child welfare.—There is no clean-cut line of demarcation between the duties of a local health authority and those of the general practitioner. Before the passing of the Act there was an obvious need for the ante-natal clinic, the children's clinic, the school minor ailment clinic and all its ancillary services, because they provided a service which otherwise was not available free of charge except to insured persons. To-day it must be remembered that if a mother needs advice regarding her children or minor ailment treatment she is entitled to it from her general practitioner under the National Health Service scheme. We therefore get the anomalous position of the school doctor or the child welfare officer being told to see a patient at a maternity and child welfare or school clinic but not to prescribe at the expense of the local health authority, but to refer the patient to her own doctor to get a prescription under the National Health Service Act. The alternatives are: to give advice only, which is administratively difficult, to scrap the clinics and send patients to the general practitioner, which is unwise, or to allow the doctors in welfare clinics and school clinics to prescribe under the National Health Service Act. This is the obvious solution. The difficulty lies in the fact that there would be two doctors prescribing for one patient, that is, the local health authority's doctor at the clinic and possibly a general practitioner. I think this is a theoretical objection for it could easily have occurred before July 5, 1948, yet in fact no difficulty did arise therefrom.

Health centres. These must be provided, maintained and staffed as far as non-professional personnel is concerned, by the local health authority. General practitioners will be supplied to work thereat by the local executive council; specialists by the hospital service. At these health centres many of the local authority's functions will be stationed. I cannot persuade myself that this manifold provision of services in one health centre is satisfactory, and the Government should make up its mind whether or not it really does want the local health authority to provide actual treatment services or whether it wants such services provided by them temporarily until such time as they can be taken over either by the local executive councils or the hospital service.

Infectious diseases.—Notification is to the medical officer of health of the local authority, be it a county borough, a non-county borough, an urban or a rural district council. Vaccination and immunization are the function of the county or the county borough. I think this is most unfortunate. Surely the medical officer of health who has to deal with the prevention of epidemic disease should also be responsible for and have all information concerning the immunity of the population whose health he protects.

Many of these difficulties have been got over administratively by appointing the district medical officer of health as assistant county medical officer. In some cases local committees, called area committees, intervene between the county medical officer and the assistant working in those areas. I do not think this promotes an integrated service throughout the whole county, and it certainly causes administrative delay and unnecessary expenditure.

Pædiatrics and obstetrics.—It is now proposed to divide maternal care from the care of children. Pædiatricians will look after children under 5 and school children, and obstetricians will conduct ante-natal and post-natal clinics. It is further suggested that pædiatricians shall be associated with a hospital for children or the pædiatric department of a general hospital, and obstetricians with a lying-in hospital or the obstetric department of a general hospital. This sounds easy but it does mean one person serving two masters.

The matter becomes still further complicated when we are told that in future our clinics should be manned by general practitioners in order that they may participate in the preventive health services. This means that we shall have a general practitioner receiving his fees from the local executive council, being paid for his clinic work by the local health authority, and yet also being on the staff of a special hospital and being paid thereby. He will have in fact three masters. If it is really the intention that pædiatricians shall look after children, and obstetricians the expectant and nursing mothers, then I think the clinics must be staffed and manned by the hospitals.

Incidentally, wholetime maternity and child welfare officers have been a success and I see no reason why they should be abolished.

The hospital service.—No local health authority now possesses hospital beds, and I think some of them are finding it extremely difficult to administer a service without the backing of beds. I know that there is liaison between Regional Hospital Boards and Local Health Authorities, but liaison with somebody who controls hospital beds is a very different story from controlling them oneself.

Now the Regional Hospital Boards have set up Management Committees to look after one, two or more hospitals. There would have been a better integration if the public health committees of the local authorities or of selected local authorities had been made the hospital management committees. In this way there would have been a wise integration of hospital and local authority services, still leaving the general control and planning of the hospitals to the Regional Boards, while avoiding the setting up of a large number of new committees and the employment of a large number of additional officers.

[*October* 26, 1949.

The History of the Discovery of Addison's Disease

By P. M. F. BISHOP, D.M.

THE PAPER TO THE SOUTH LONDON MEDICAL SOCIETY

A HUNDRED years ago, on Thursday, March 15, 1849, Dr. Addison, at the request of the President, John Hilton, proceeded to describe, before the South London Medical Society: "A remarkable form of anæmia, which, although incidentally noticed by various writers, had not attracted, as he thought, by any means the attention it really deserved. It was a state of general anæmia incident to adult males, and had for several years past been with him a subject of earnest inquiry and of deep interest. It usually occurs between the ages of 20 and 60; sometimes proceeding to an extreme degree in a few weeks, but more frequently commencing insidiously, and proceeding very slowly, so as to occupy a period of several weeks, or even months, before any very serious alarm is taken either by the patient or by the patient's friends. Its approach is first indicated by a certain amount of languor and restlessness, to which presently succeed a manifest paleness of the countenance, loss of muscular strength, general relaxation or feebleness of the whole frame, and indisposition to, or incapacity for, bodily or mental exertion. These symptoms go on increasing with greater or less rapidity: the face, lips, conjunctivæ, and external surface of the body, become more and more bloodless; the tongue appears pale and flabby; the heart's action gets exceedingly enfeebled, with a weak, soft, unusually large, but always strikingly compressible pulse; the appetite may or may not be lost; the patient experiences a distressing and increasing sense of helplessness and faintness; the heart is excited, or rendered tumultuous in its action, the breathing painfully hurried by the slightest exertion, whilst the whole surface bears some resemblance to a bad wax figure: the patient is no longer able to rise from his bed; slight œdema perhaps shows itself about the ankles; the feeling of faintness and weakness becomes extreme, and he dies either from sheer exhaustion, or death is preceded by signs of passive effusion or cerebral compression. In three cases only was there an inspection of the body after death, and *in all of them was found a diseased condition of the suprarenal capsules*. Dr. Addison inquired if it were possible for all this to be merely coincidental? It might be so, but he thought not, and making every allowance for the bias and prejudice inseparable from the hope or vanity of an original discovery, he confessed that he felt it very difficult to be persuaded that it was so. On the contrary, he could not help entertaining a very strong impression that these hitherto mysterious bodies—the supra-renal capsules—may be either directly or indirectly concerned in sanguification; and that a diseased condition of them, functional or structural, may interfere with the proper elaboration of the body generally, or of the red particles more especially. At all events, he considered that the time had arrived when he felt himself warranted in directing the attention of the profession to these curious facts."

THE 1855 MONOGRAPH

Little attention appears to have been paid to these observations, and it was six years before Addison himself again brought this condition to the notice of the medical profession by the publication of a short monograph "On the Constitutional and Local Effects of Disease of the Supra-renal Capsules" in the introduction to which he says: "There are still, however, certain organs of the body the actual functions and influence of which have hitherto entirely eluded the researches, and bid defiance to the united efforts of both physiologist and pathologist.

"Of these, not the least remarkable are the 'supra-renal capsules', the *atrabiliary* capsules of Caspar Bartholinus; and it is as a first and feeble step towards inquiry into the functions

and influence of these organs suggested by pathology, that I now put forth the following pages."

Every author who writes upon Addison's disease acknowledges that Addison's original description of the condition has not been improved upon either in respect of the accuracy and the thoroughness of his observations, or in the eloquence of his narrative. We shall do well therefore to browse for a few moments among the pages of what is undoubtedly one of the outstanding medical classics of the nineteenth century.

"It will hardly be disputed", it begins, "that at the present moment the functions of the supra-renal capsules, and the influence they exercise in the general economy, are almost or altogether unknown. The large supply of blood, which they receive from three separate sources; their numerous nerves, derived immediately from the semilunar ganglia and solar plexus; their early development in the fœtus; their unimpaired integrity to the latest period of life; and their peculiar gland-like structure—all point to the performance of some important office: nevertheless, beyond an ill-defined impression, founded on a consideration of their ultimate organization, that, in common with the spleen, thymus, and thyroid body, they in some way or other minister to the elaboration of the blood, I am not aware that any modern authority has ventured to assign to them any special function or influence whatever.

"To the physiologist and to the scientific anatomist, therefore, they continue to be objects of deep interest; and doubtless both the physiologist and anatomist will be inclined to welcome and regard with indulgence the smallest contribution calculated to open out any new source of inquiry respecting them. But if the obscurity which at present so entirely conceals from us the uses of these organs justify the feeblest attempt to add to our scanty stock of knowledge, it is not less true, on the other hand, that any one presuming to make such an attempt ought to take care that he do not, by hasty pretensions, or by partial and prejudiced observation, or by an over-statement of facts, incur the just rebuke of those possessing a sounder and more dispassionate judgment than himself.

"Under the influence of these considerations I have for a considerable period withheld, and now venture to publish, the few facts bearing upon the subject that have fallen within my own knowledge, believing, as I do now, that these concurring facts, in relation to each other, are not merely casual coincidences, but are such as admit of a fair and logical inference —an inference that, where these concurring facts are observed, we may pronounce with considerable confidence the existence of diseased supra-renal capsules.

"As a preface to my subject, it may not be altogether without interest or unprofitable to give a brief narrative of the circumstances and observations by which I have been led to my present convictions.

"For a long period I had from time to time met with a very remarkable form of general anæmia, occurring without any discoverable cause whatever—cases in which there had been no previous loss of blood, no exhausting diarrhœa, no chlorosis, no purpura, no renal, splenic, miasmatic, glandular, strumous, or malignant disease.

"Accordingly, in speaking of this form in clinical lecture, I perhaps with little propriety applied to it the term 'idiopathic' to distinguish it from cases in which there existed more or less evidence of some of the usual causes or concomitants of the anæmic state.

"It makes its approach in so slow and insidious a manner that the patient can hardly fix a date to his earliest feeling of that languor which is shortly to become so extreme. The countenance gets pale, the whites of the eyes become pearly, the general frame flabby rather than wasted; the pulse, perhaps large, but remarkably soft and compressible, and occasionally with a slight jerk, especially under the slightest excitement; there is an increasing indisposition to exertion, with an uncomfortable feeling of faintness or breathlessness on attempting it; the heart is readily made to palpitate; the whole surface of the body presents a blanched, smooth and waxy appearance; the lips, gums, and tongue seem bloodless; the flabbiness of the solids increases; the appetite fails; extreme languor and faintness supervene, breathlessness and palpitations being produced by the most trifling exertion or emotion; some slight œdema is probably perceived above the ankles; the debility becomes extreme. The patient can no longer rise from his bed, the mind occasionally wanders, he falls into a prostrate and half-torpid state, and at length expires. Nevertheless, to the very last, and after a sickness of, perhaps, several months' duration, the bulkiness of the general frame and the obesity often present a most striking contrast to the failure with exhaustion observable in every other respect.

"With perhaps a single exception the disease, in my own experience, resisted all remedial efforts, and sooner or later terminated fatally.

"It was whilst seeking in vain to throw some additional light upon this form of anæmia that I stumbled upon the curious facts which it is my more immediate object to make known to the profession; and however unimportant or unsatisfactory they may at first sight appear, I cannot but indulge the hope that, by attracting the attention and enlisting the co-operation

of the profession at large, they may lead to the subject being properly examined and sifted, and the inquiry so extended as to suggest, at least, some interesting physiological speculation, if not still more important practical indications.

"The leading and characteristic features of the morbid state to which I would direct attention are, anæmia, general languor and debility, remarkable feebleness of the heart's action, irritability of the stomach, and a peculiar change of colour in the skin, occurring in connexion with a diseased condition of the 'supra-renal capsules'. We discover a most remarkable and, so far as I know, characteristic discoloration taking place in the skin —sufficiently marked, indeed, as generally to have attracted the attention of the patient himself or of the patient's friends.

" This discoloration pervades the whole surface of the body, but is commonly most strongly manifested on the face, neck, superior extremities, penis, and scrotum, and in the flexures of the axillæ and around the navel.

" It may be said to present a dingy or smoky appearance, or various tints or shades of deep amber or chestnut-brown; and in one instance the skin was so universally and so deeply darkened that but for the features the patient might have been mistaken for a mulatto.

"In some cases the discoloration occurs in patches, or perhaps rather certain parts are so much darker than others as to impart to the surface a mottled or somewhat chequered appearance; and in one instance there were, in the midst of this dark mottling, certain insular portions of the integument presenting a blanched or morbidly white appearance, either in consequence of these portions having remained altogether unaffected by the disease, and thereby contrasting strongly with the surrounding skin, or, as I believe, from an actual defect of colouring matter in these parts.

"This singular discoloration usually increases with the advance of the disease; the anæmia, langour, failure of appetite, and feebleness of the heart, become aggravated; a darkish streak usually appears on the commissure of the lips: the body wastes, but without the emaciation and dry, harsh condition of the surface, so commonly observed in ordinary malignant cases; the pulse becomes smaller and weaker; and without any special complaint of pain or uneasiness the patient at length gradually sinks and expires."

The State of Knowledge Concerning the Adrenal Glands Before 1849

Addison himself indicated, in the passages which I have just quoted from his monograph, that "the functions of the supra-renal capsules, are almost or altogether unknown". In the beautiful copperplates of human anatomy which Eustachius completed in 1552, but which were preserved in the Vatican Library until Pope Clement XI gave them to his physician Lancisi for publication in 1714, the adrenals are shown. Jean Riolan, bitter critic of William Harvey, named them the "supra-renal capsules" in 1629, though some years previously in Copenhagen, Caspar Bartholinus the elder, grandfather of that Caspar Bartholinus who described the vaginal glands, believed they contained black bile in their "cavity". A hundred years later the Académie des Sciences of Bordeaux offered a prize for an essay on "Quel est l'usage des glandes surrénales?" Apparently no one could put forward even a plausible theory, for the adjudicator recommended that the prize should not be awarded.

Another hundred years later in 1841, François Magendie, the physiological mentor of the great Claude Bernard, made the somewhat enigmatic remark that as no one believed any longer in black bile, the adrenals "had ceased to be secreting agents".

The comparatively large size of the organs in the fœtus had led to the suggestion that they were the fœtal kidneys, which ceased to have any function after birth.

Development of Knowledge of the Adrenals Subsequent to 1849

Addison's brilliant discovery was like a comet in a starless sky. It flashed across the scene and disappeared. Some people, especially in this country, even denied its existence. The prophet was not to be without honour, however, for Trousseau in 1856, the year after the publication of the monograph, named the condition "La maladie d'Addison" and that impetuous and ebullient figure Charles Edouard Brown-Séquard lost no time in collecting together fifty-one rabbits, eleven dogs, cats, mice and pigs, and depriving them of their adrenals, insisting when they all succumbed that they had died of Addison's disease and that the adrenal glands contained a life-preserving material. This, the first conception of an endocrine secretion, was looked upon with scepticism by some of Brown-Séquard's contemporaries, who were used to the sudden changes in his chequered career, and the wild ideas that chased each other through his impulsive mind, and they were inclined to attribute the death of his animals to more cynical causes.

From 1856, when Brown-Séquard performed his classical experiments, onwards for

nearly forty years nothing further was added to the knowledge of the adrenals. In 1894 Oliver and Schäfer demonstrated the presence of a pressor substance in the adrenal medulla. In 1901, Takamine and Aldrich independently isolated adrenaline in crystalline form, Aldrich giving it the empirical formula of $C_9H_{13}NO_3$; and in 1904 Stolz synthesized it. It thus became the first hormone to be chemically isolated, have its structure established and to be synthesized. In 1917 Rogoff and Stewart began the series of researches which established cortical extracts as possessing life-preserving properties. In 1919 Cannon propounded his "emergency" theory of adrenal medullary function. In 1928 Szent-Györgyi embarked upon his search for a powerful reducing agent in the adrenal cortex and ended up by discovering vitamin C. In 1930 Swingle and Pfiffner prepared a cortical extract which maintained life in adrenalectomized dogs and which was subsequently employed in the treatment of Addison's disease. In 1936 Kendall isolated corticosterone in crystalline form. In 1937 Reichstein prepared deoxycorticosterone acetate synthetically. In 1938 Simpson employed it in the treatment of Addison's disease. In 1946 17-hydroxy-11-dehydro-corticosterone (Kendall's Compound E) was prepared from deoxycholic acid by Sarrett, working at the Merck Research Laboratories, and in 1949, exactly one hundred years after Addison was addressing the South London Medical Society, Philip Hench, of the Mayo Clinic, made the startling announcement that Compound E or "cortisone" could completely relieve the symptoms of rheumatoid arthritis.

The Background of Addison's Discovery

Was Addison's discovery a lucky chance, or did he deserve the fame it has subsequently bestowed upon his name?

Undoubtedly the condition was not a new disease. Marañón, the great Spanish physician, endocrinologist and historian, has diagnosed in retrospect a case of Addison's disease in a priest at Escorial, the hamlet where Philip the Second was later to build in the shape of the grill on which St. Lawrence was martyred, that magnificent edifice, part monastery, part cathedral, part palace, in gratitude for the victory of St. Quentin. The monk's illness occurred in 1554, the year that Mary of England became Philip's wife.

Addison was lucky not to have been forestalled on at least five occasions. In his own hospital his senior colleague, the great Richard Bright, had, as early as 1831, observed and recorded a case of Addison's disease, and had preserved the adrenal glands which were tuberculous. Addison, in reporting on this case again, in his 1855 monograph, writes : "It does not appear that Dr. Bright either entertained a suspicion of the disease of the capsules before death, or was led at any period to associate the colour of the skin with the diseased condition of these organs, although his well-known sagacity induced him to suggest the probable existence of some internal malignant disease." In 1823, Schotte recorded a typical case, and Kirkes also described a case before Addison's monograph was published. In 1856 Sibley recorded another case at the Middlesex Hospital. In 1846, Aran published a series of cases of supposed pancreatic disease one of which is given in full detail and is clearly a case of Addison's disease. Aran, however, mistook the site of the abscess found on opening the abdomen at autopsy. The pus originated in the adrenal, but he thought it came from the pancreas.

Addison's achievement was in realizing that the adrenal disease was the cause of the clinical syndrome which he so vividly described, and the following considerations will show that this was no lucky coincidence.

(1) *Addison as a Dermatologist*

In the first place, Addison was especially intrigued by the pigmentation in this condition because he had a singular interest in skin disorders and might well have made a name and a fortune for himself as a dermatologist had he so wished. It is, however, one of the paradoxes of this fascinating story that the founder of clinical endocrinology abhored specialism in medicine. He had studied under Thomas Bateman, the disciple of Robert Willan, the founder of British dermatology, and the mantle of Bateman had fallen upon Addison's shoulders. He is the only person to have enjoyed the distinction of having three diseases called after him: Addison's anæmia, Addison's disease and Addison's keloid or localized scleroderma. He also gave the first description of xanthoma. During his many years of intimate association with Guy's Hospital he was responsible for building up the unique collection of wax models of skin conditions fashioned by Joseph Towne, the modeller, whom Astley Cooper introduced to Guy's and who served the hospital in this capacity for over fifty years. The famous marble bust of Thomas Addison, which Wilks thought to be such an excellent likeness, is by Towne.

(2) *Addison as Diagnostician*

Secondly, Addison was outstandingly famous as a diagnostician. To him the diagnosis of a patient's illness was a problem that must be solved, however long it took him to do so,

darting from one side of the bed to the other because he was deaf in one ear, and however much he might weary the patient or his student audience in the process. He had been known to return to the Hospital in the middle of the night, much to the astonishment of the ward sister, because just as he had got into bed he realized that he had forgotten to examine a patient he had seen in the afternoon, for a hernia. He was insistent on detailed and accurate recording of clinical observations, and introduced the systematic writing of ward clerk's reports at Guy's. He spent many hours in the dead house, trying to unravel the cause of death in some case the diagnosis of which had eluded him; and it must be remembered that in these days post-mortem examinations were the exception rather than the rule. His fame as a diagnostician made him one of the first "consulting physicians" as we understand the term to-day. The fashionable Victorian physician seldom had cases referred to him by a general practitioner or a colleague. His practice depended on the extent to which he was known to the public, and patients would call at his house and be herded into his waiting room on the off-chance of his being able to see them. Many fashionable physicians such as Gull resigned their hospital appointments comparatively early in life in order to devote more time to the profitable pursuit of their private practices. Gull, for instance, died worth £344,000.

Addison was not a physician of this type. He spent a considerable proportion of his time in the hospital, and though he was a man of forceful personality, who commanded the loyal and devoted respect of his students, he did not always completely satisfy the patient or his relatives, for he was too honest to think much about treatment, which at that time was practically non-existent. Nevertheless his opinion on diagnosis was sought constantly by his colleagues.

(3) *Addison in* 1849 *and* 1855

Addison's discovery was not due to the intuitive brilliance of youthful genius, but rather to the rigid discipline of the trained and mature observer. The monograph of 1855 was the last of his publications, and it is probable that neither he nor his most intimate friends appreciated that it would in time become one of the most famous contributions to medical literature. Indeed it is clear that his brief communication in 1849 to the South London Medical Society was made with diffidence, and would quite possibly never have been made at all but for John Hilton, his surgical colleague, and author of that great surgical classic "Rest and Pain". Addison allowed six years to elapse before elaborating the subject of his modest and unpretentious communication, and there seems little doubt that he would never have written the monograph, but for the diligent preparation of the material and the loyal, and diplomatic, encouragement of his friends and especially of a young man named Samuel Wilks, not yet on the Staff of Guy's.

Addison was anything but a prolific writer, and considering that he was the first to teach the clinical signs of fatty liver, to describe the symptoms and pathology of appendicitis, to demonstrate that pneumonia is due to an inflammatory exudate into the alveoli and not into the non-existent parenchyma of the lung, to demonstrate that phthisis is a mixed infection, that xanthoma is associated with jaundice, as well as describing pernicious anæmia and Addison's disease, the 13 papers which were collected together by Wilks and Daldy for publication by the New Sydenham Society, indicate a degree of literary restraint which might well be emulated by many less eminent and originally-minded writers.

Addison therefore was an old rather than a young man when he wrote his famous monograph. He was in fact 60, and Senior Physician to Guy's Hospital. His influence in the Hospital at this time was greater than that of any Guy's man, including Richard Bright, and except possibly Astley Cooper. He had always been a brilliant teacher. In his early days at Guy's he had earned £800 a year teaching students outside the Hospital Materia Medica. Sir William Hale-White, whose "Materia Medica" is still one of the most authoritative books on the subject, says: "He even made the dry bones of Materia Medica attractive."

He had devoted literally his entire life for the past thirty years to Guy's and the advancement of medicine. He was a bachelor up to the age of 52, and he had no hobbies or recreations, other than an annual visit to Lanercost in Cumberland from which his yeoman ancestry was derived.

Indeed his single-minded devotion to Guy's, his introspective and melancholic nature, and his extreme embarrassment when called upon to speak in public—he confessed that he used to shake with fright whenever he addressed the Guy's Physical Society, a mere student organization—prevented him from acquiring the marks of distinction which his more extroverted colleagues collected with ease. He was never President of the Royal College of Physicians; he was neither knighted nor did he become a baronet, like Gull, or Wilks after him, and Astley Cooper before him; he was not elected a Fellow of the Royal Society. He did, however, become President of the Medico-Chirurgical Society—now the Royal Society of Medicine.

His introspective and melancholic nature was the secret cross he had to bear. He did his

best to overcome it. Wilks, who knew him best, says he was an affable man. His students feared him, respected him and loved him. When he resigned from Guy's they asked him to come back, though he was 65 at that time. The last letter he ever wrote shows how much he appreciated their affection. "I can truly affirm", it says, "that I ever found my best support and encouragement in the generous gratitude and affectionate attachment, as well as my proudest reflections, in the honorable and most exemplary conduct of my pupils." He had been subject to fits of profound depression all his life. They had led him to rise from his bed of insomnia and pace the streets, where he occasionally met some colleague hastening home from a late call. To those who did not know him, these nocturnal pacings would be wrongly construed, and it was whispered that he sought the company of the ladies of the street. On many occasions he had contemplated suicide. In 1860 he retired from public life and from his beloved Guy's, because he thought his younger colleagues and particularly William Gull wanted to deprive him of his position. He went to live in Brighton and, though constantly guarded by two attendants, he succeeded in evading them and threw himself out of a window, to end a selfless though highly introspective life.

The Influence of "King" Harrison on Addison's Career

To turn for a moment to his early life. His appointment to the Staff of Guy's was yet another indication of the prescience of that autocratic personality who was one of the three men who have made Guy's Hospital. The first was Thomas Guy, a governor of St. Thomas's who saw the need to establish a hospital to care for the chronic sick and the insane. The last was Lord Nuffield, whose remarkable benefactions not only to Guy's but to Medicine as a whole have led us at Guy's to erect a statue to his honour during his lifetime. The third man was Benjamin Harrison, Treasurer of the hospital for fifty-one years, from 1797–1848. He was personally responsible for the appointment to the Hospital of Astley Cooper, Richard Bright, Thomas Addison, William Gull and Thomas Hodgkin. The case of Addison is especially noteworthy. Addison had obtained his M.D. in Edinburgh, and he came to Guy's five years later in 1820 as an ordinary student, but owing to the preferment exercised by "King" Harrison he was appointed to the staff in 1824. His only serious rival was Dr. Edward Seymour who had actually received a recommendation to the Governors from the future King William IV.

The Immediate Consequences of Addison's Monograph

In his communication to the South London Medical Society Addison was obviously describing pernicious anæmia, though some of the cases on which this paper was based were examples of Addison's disease. In the 1855 monograph, Addison had not altogether shed the idea of "idiopathic" anæmia, and had yet, on the other hand, gone too far by including cases of malignant disease of the adrenal glands. No one could easily mistake to-day, however, the classical description which he applied to the clinical condition which we now know as Addison's disease.

The monograph was not universally hailed with acclamation. Even twenty years later when Greenhow delivered his Croonian Lectures on Addison's disease he perceived a disinclination to accept the condition as a clinical entity. Papers were written in Germany and France in disproof of its existence. In England specimens were exhibited for years at the Societies, and discussions took place upon them before doubts ceased to be thrown upon the reality of the condition. Two or three papers read before the Medico-Chirurgical Society (now our Royal Society of Medicine) were not approved for publication, so that no record can be found in the *Transactions* of this remarkable discovery. Addison was deeply hurt at this as he had not long before been President of the Society. At Edinburgh, where Addison had obtained his M.D., Hughes Bennett and other professors would not acknowledge the disease. But in Paris, Trousseau gave the condition Addison's name, and Brown-Séquard founded experimental endocrinology after reading Addison's monograph.

In England, however, Addison had one or two staunch supporters. Jonathan Hutchinson reported further cases with post-mortem findings, and Samuel Wilks loyally unravelled the misunderstandings concerning idiopathic anæmia and Addison's disease.

Oliver Wendell Holmes, in "The Poet at the Breakfast Table" describes the following conversation between the poet and Dr. Franklin, whom he consults on account of a discoloration on the forehead.

' "The colour reminds me", said Dr. Franklin, "of what I have seen in a case of Addison's disease, Morbus Addisonii."

I said I thought the author of the *Spectator* was afflicted with a dropsy to which persons of sedentary and bibacious habits are liable.

"The author of the *Spectator*!" cried out Dr. Franklin; "I mean the celebrated Dr. Addison, the inventor, I would say, discoverer of the wonderful new disease called after him."

"And what may this valuable invention or discovery consist in?" I asked, for I was anxious to know the nature of the gift which this benefactor of the race had bestowed upon us.

"A most interesting affection, and rare too. Allow me to look closely at that discoloration once more for a moment. *Cutis aenea*—bronze skin they call it sometimes—extraordinary pigmentation; a little more to the light if you please. Ah! now I get the bronze-colouring admirably, beautifully. Would you have any objection to showing your case to the societies of medical improvement and medical observation?"

"May I ask if any vital organ is commonly involved in this interesting complaint?" I said faintly.

"Well sir", the young doctor replied, "there is an organ which is—sometimes—a little—touched I may say; a very curious and—ingenious little organ or pair of organs. Did you ever hear of the *capsulæ suprarenales*?"

"No", said I, "is it a mortal complaint?" getting nervous.

"It isn't a complaint—I mean they are not a complaint; they are two small organs, as I said, inside of you, and nobody knows what is the use of them. The most curious thing is, that when anything is the matter with them, you turn of the colour of bronze. After all I didn't mean to say I believed it Morbus Addisonii; I only thought of that when I saw the discoloration."

So he gave me a recipe which I took care to put where it could do no hurt to anybody, and I paid him his fee (which he took with the air of a man in the receipt of a great income), and said good morning.'

Comparison Between the Discovery of Addison's Disease, Gull's Disease and Cushing's Syndrome

It has always seemed to me interesting to compare the circumstances under which Addison's disease, Gull's disease and Cushing's syndrome were launched upon the medical profession.

Addison, a morose and parochial physician diffidently describing first pernicious anæmia, and then, goaded on to more spectacular publication, produced a monograph which is still a masterpiece of clinical virtuosity, accurate and even now up to date in every detail. This monograph, now one of the most famous in medical literature, was the subject of bitter controversy when it first appeared.

Gull, Napoleonic, epigrammatic extrovert, the "physician of fashion", as he once described himself, of the 1870's, who had lately been called in by Sir William Jenner to attend the Prince of Wales in his attack of typhoid fever, and had won the heartfelt thanks not only of the Nation but also of a mother who had lost her beloved husband from the same complaint: Gull, now Sir William, and one of the most famous men in England, read a paper in 1873 to the Clinical Society of London "On a cretinoid state supervening in adult life in women". The paper was brief and not very different from the usual type of communication that was constantly reported in the *Transactions* at that time. It was, however, by Sir William Gull, and that sufficed to draw attention to it. This paper contained the first description of myxœdema, and though William Ord elaborated the clinical syndrome in 1877 and called it "myxœdema" there was no doubt from the beginning that it was Gull who discovered the condition. It is, however, interesting to note that though it is quite frequently still spoken of on the Continent and in America as "Gull's disease", I found it necessary in announcing the title of a clinical lecture I was to give at Guy's Hospital last year on "Gull's Disease" to add in brackets "Myxœdema".

Cushing's syndrome was described by Harvey Cushing in 1932 in the *Bulletin of the Johns Hopkins Hospital*. He recorded 12 cases of this syndrome, and as he told me himself he travelled sometimes many hundreds of miles at short notice to be present at the post-mortem of some of the cases reported. Once again the eponym was applied by someone in another country (Bishop and Close), this time in England, and in this case it is possible that the eponym is well applied, for we still are not certain where the lesion lies, whether in the basophil cells of the pituitary, in the adrenal cortex, or whether, in some cases, there is a lesion at all. Cushing, at the time of his description of this syndrome, was the most famous neurosurgeon in the world. Whatever he might describe would instantly attract attention.

Cushing's discovery is not so very long ago. We are apt to think that Medicine has become so complicated, and so dependent on the laboratory and on team work, that no one individual can stand out as a giant among his peers in this rapidly progressing subject of endocrinology. This is surely not true. Fuller Albright, for instance, still a young man, is a prodigious giant of clinical and biochemical endocrinology, and it is my belief that the days of discovery of important and exciting syndromes have not yet passed, and that members of

this Section will continue to emulate the brilliant example of Thomas Addison, the founder of endocrinology, a hundred years ago.

Studies in Chronic Retention

PRESIDENT'S ADDRESS

By Professor CHARLES WELLS

IN my Unit, we have, for three years, been considering renal function in prostatism and other obstructive states. This is an account of a small group of patients studied in considerable detail over a period of a year, certain of the cases having been followed for a longer period. The labour of research has been borne chiefly by Mr. Raphael Marcus. The operative procedure has, in all cases, been that advocated by Mr. Wilson Hey, with certain minor modifications. No patient has been refused operation, and cases of complete obstruction have been dealt with by immediate prostatectomy without preliminary catheterization. Intravenous pyelography has preceded surgery in all cases.

The smooth convalescence usual after the Wilson Hey procedure has enabled us to make comparable observations in all our cases.

Availing ourselves of the evidence of intravenous pyelography we have for our own purposes classified our cases pre-operatively into:

(1) Those in whom the upper urinary tract is normal, or almost normal.

(2) Those in whom there is a marked degree of hydronephrosis due to back pressure, and

(3) Those in whom there is such back pressure that there is no renal shadow and very little evidence of any excretory activity visible in any part of the urinary tract.

It is surprising that with even the highest degrees of chronic retention we have found a number of cases with completely intact upper urinary tracts.

The following are four striking examples:

CASE I.—W. H. M., aged 72. He reported with his bladder distended to above the umbilicus and he looked gravely ill. His intravenous pyelograms disclosed a normal upper tract.

CASE II, F. R., and CASE III, J. D., were two patients who were catheterized in Canada for the relief of chronic retention which had become complete. They crossed the Atlantic without mishap with catheters tied in and successfully underwent prostatectomy. The anatomy of the upper tract was normal.

CASE IV.—C. C. W., aged 65. This patient was rushed into hospital because of his greatly distended bladder. Intravenous pyelograms showed normal kidneys (*see* Fig. 1 which illustrates this case and is typical also of the other three).

It is of interest that two of these patients actually crossed the Atlantic with catheters tied in the urethra and arrived in this country in perfect condition. I think it is a fair assumption that their easy journey was due to the fact that their kidneys and ureters were intact. Two other assumptions follow. Firstly, that patients fortunate enough to have suffered no renal damage due to back pressure should do well whatever the basis of their operative treatment, and, further, that to subject such patients to a tedious two-stage procedure because the bladder is dilated is unjustifiable and a waste of time.

When the figure is available at the time of pre-operative assessment it will be found that these patients, even with a high degree of bladder distension, mostly have a relatively low blood urea. In the two non-catheterized patients described, the figures were 35 mg.% and 38 mg.%. The condition is a clinical entity which should be carefully considered because of its favourable operative prognosis.

The intermediate group in which there is a moderate degree of back pressure is naturally not easy to define. Amongst the examples which I quote is one which demonstrates that a low blood urea alone is not proof of an intact upper tract.

CASE V.—C. W. H., aged 71, had had overflow incontinence for six weeks. His blood urea was 35 mg.%. Intravenous pyelograms at five minutes revealed no collection of "Pyelectan". At fifteen minutes the dilated calyces were seen and the pyelogram at thirty minutes showed gross hydronephrotic changes and tortuous and dilated ureters (Fig. 2). Figs. 4 and 5 show his progress after operation.

How this change in the upper urinary tract becomes established is a matter about which we have insufficient evidence to be dogmatic. We have attempted a few experiments in producing reflux up the ureters both in man and experimental animals. So far as our evidence goes it suggests that the intact ureter does not allow fluid to be forced up and it suggests further that in the prostatic subject, once the process starts, there is a preliminary period in which the lower ureter only is dilated. We think it likely that once established this progresses relatively quickly to affect the whole ureter, including the renal pelvis, with the production of hydronephrosis. My impression is that blood ureas are normally either below 40, indicating little back pressure, or up to 100 or more, indicating hydronephrosis. Few are caught in between. I am not prepared to place much emphasis upon the significance of the preliminary stage of back pressure change, except in so far as it elucidates the mechanism of production of hydronephrosis and the ascent of infection to the kidney level. Fig. 3 (*a*) (Case VI) shows an example of ureteric reflux and (*b*) the increased back pressure caused by attempting micturition with the urethra clipped.

FIG. 1 (*Case* IV).—C. C. W., aged 65. Note bladder distended to level of interspace L 3/4 with anatomically normal ureters and kidneys.

FIG. 2 (*Case* V).—C. W. H., aged 71. Gross dilatation of the upper tract associated with chronic retention due to enlargement of the prostate. Film at thirty minutes after injection of dye.

Altogether there have been amongst our cases, during the relevant year of research, 28 with such a degree of residual urine as to qualify for the description of "chronic retention". 80 to 100 ounces of urine have usually been found in the bladder. Of these 28, 5 have fallen into the first category with normal pyelograms, 16 into the second with dilated pelves, and 7 into the third with no demonstrable function. Every case has been subjected to operation, 9 as emergencies[1] without previous investigation, other than intravenous pyelography, and 19 as elective procedures. Of 18 consecutive cases operated upon by me personally none has died. (One other prostatectomy, a known carcinoma who had failed to respond to stilbœstrol, did die. His death was due to dehydration with œdema.) Of the 10 operated upon by others of the team one died. He was too ill to co-operate and could not be got out of bed. He developed hypostatic pneumonia to which he succumbed. He was one of the 7 in the small third group, with no demonstrable function. He should have been refused prostatectomy because of his inability to co-operate (Wells, 1949).

[1] These do not represent all the patients operated upon as emergencies. Simple acute retentions without previous chronic retention are not included in this study.

When we realized what a uniform and smooth convalescence could with confidence be expected in these cases we decided to intensify our investigations during and after the time of operation.

It will serve our purpose best if we turn now to illustrate this by describing in detail one of the patients whose X-ray, Fig. 2, has already been shown above.

C. W. H. (Case V), aged 71, had had overflow incontinence for six weeks. We have already seen in fig. 2 the hydronephrosis present before operation. His blood urea at that time was 35 mg.%. Fig. 4 shows his pyelogram eighteen days after prostatectomy. Fig 5 is one year after operation. His blood urea was then 29 mg.%

FIG. 3A (*Case* VI).—Chronic retention with reflux up the right ureter.

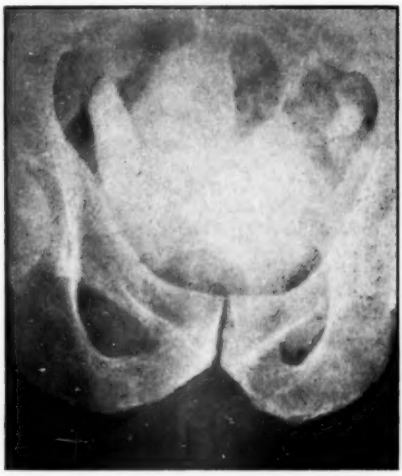

FIG. 3B (*Case* VI).—The same as 3A, taken a few moments later, on attempting to micturate with the urethra clamped. Increased ureteric reflux is demonstrated.

FIG. 4 (*Case* V).—C. W. H., aged 71. Intravenous pyelogram showing improved condition of upper tract eighteen days after operation.

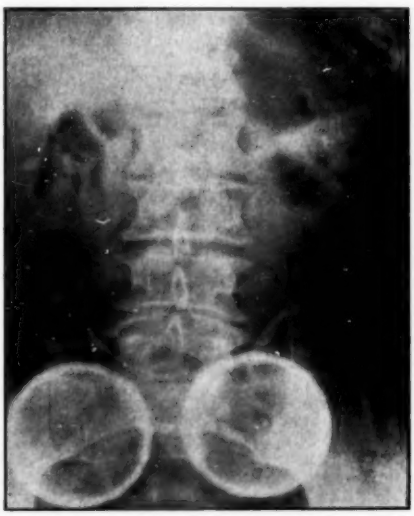

FIG. 5 (*Case* V).—C. W. H., aged 71. I.V.P. Ten minutes after injection of dye one year after prostatectomy.

Probably the most impressive single fact in this case is the amount of recovery which has taken place in the previously dilated upper urinary tract. The blood urea was never seriously raised and fluctuated very little. Although it has come down the change was not great. The change in his general condition has been quite remarkable. At the time of operation there was marked œdema of the legs below the knee, and this cleared rapidly during the first few days. This is a phenomenon which we have observed in a small number of cases. In one in particular (Case VII, G. M., aged 74) both legs were very heavily waterlogged and there was œdema round the pelvis and sacrum. The urinary output, without forcing fluids, during the first few days was as follows: First day – 108 oz., second day – 142 oz., third day – 130 oz. Within one day the œdema of the legs had disappeared. The blood urea was 120 mg.% at operation ; 50 mg.% next morning ; and 45 mg.% forty-eight hours after prostatectomy.

It would appear that in the presence of prostatic obstruction water can be voided from the bladder only at a certain rate and therefore in a certain limited total quantity in the course of twenty-four hours. Any excess of water becomes locked up in the tissues as œdema. The moment the obstruction is released the fluid shifts back from the tissue spaces into the circulation and is voided with a consequent diuresis out of proportion to the fluid taken by mouth.

The very striking change in the pyelograms in the case I have just described is characteristic of the patients in whom there is demonstrable function with some back pressure.

In Case VIII (Mr. D., aged 68) Fig. 6 shows the condition before operation (A) and ten days after operation (B). Case IX (Mr. L.) had a large diverticulum which we were able to remove cleanly and completely.

The opportunity to do this at a first-stage operation is a great advantage, since the diverticulum becomes gravely infected in the course of catheter or suprapubic drainage. Once infected, its removal is fraught with difficulty and, indeed, with danger.

One of the most striking examples of rapid recovery of renal and ureteric anatomy is instanced in Case X, K. W. P. (Fig. 7 A and B). The very considerable degree of improvement within a period of five weeks in this case is most striking. Another feature of the case, however, points an even more important lesson. During his convalescence he developed a severe urinary infection with *Bacillus pyocyaneus*. In the presence of dilated ureters this infection ascended rapidly to the kidney level and with a sharp rise in temperature he became oliguric and then virtually anuric. His blood urea rose from 40 to 120 mg.%. The organism was tested for streptomycin sensitivity and a course of that antibiotic immediately instituted. At the end of the first six-hour period the urine was almost sterile and after each of the two ensuing six-hour periods it was completely sterile. Concurrently with this bacteriological improvement the general condition became better, and the excretion of urine was resumed. The infection relapsed after the withdrawal of streptomycin but not at the kidney level, and there was no further check to the excretion of urine.

Here was a clear example of surgical kidney. The advent of pyelonephritis was associated with depression of renal function and in the old days would have proved fatal. Not only does the case illustrate the value of streptomycin in relieving this previously fatal condition, but it also suggests strongly that failure of renal function is not due to rapid decompression but to the introduction of sepsis. Amongst the cases which we have observed in our own service and that of others, we have seen a number of other examples of patients in a precarious state with mounting blood urea and diminished urinary output associated with infection. In every instance the fact that the failure of renal function was due to infection has been made immediately clear by the rapid response to streptomycin. In some instances where preliminary drainage had been instituted, the improvement after streptomycin enabled the surgeon to proceed at once, and successfully, to the prostatectomy at which he had baulked in the beginning when the case was uninfected. (When sepsis has been checked with streptomycin it may be necessary to act quickly before a relapse occurs.)

It is not my purpose to discuss the merits of streptomycin in the management of urinary sepsis, but to demonstrate how the control of infection is followed by a return of renal function.

Here is a further example:

Case XI.—T. C. W., aged 68. This patient was admitted with retention of urine and cystitis following previous catheterization. His blood urea was 42 mg.% and culture of urine grew *Staph. aureus*.

20.6.48: Prostatectomy with closure of bladder.

28.6.48: Blood urea 107 mg.%. Culture of urine—*B. pyocyaneus* and *B. proteus*. Colonies too numerous to count. Both organisms inhibited by streptomycin, 32 units per millilitre.

29.6.48: Patient's condition deteriorating. Rigors and anuria. Streptomycin treatment commenced.

30.6.48: Culture of urine sterile. Blood urea 228 mg.%.

7.7.48: Blood urea 57 mg.%. Condition much improved.

18.11.48: Sterility of urine maintained. Blood urea 33 mg.%.

The next feature to which I wish to draw attention is the change in blood-urea figures after the relief of prostatic obstruction, and more particularly the rate at which that change occurs. Up to a few years ago I had always imagined that blood urea moved rather slowly and that under catheter or suprapubic drainage it was desirable to take readings at intervals of about a week. I imagined that by comparing these readings one could construct a graph which would show roughly the improvement in the case under consideration. It is now apparent that such a conception is quite valueless. Blood-urea levels change not from week to week, nor yet from day to day, but from hour to hour. In order to obtain a true picture of the relief of azotæmia following the relief of obstruction it is necessary to take very frequent readings. I have already quoted one example (Case VII, G. M.).

FIG. 6A (*Case* VIII).—Mr. D., aged 68. Condition of upper tract before prostatectomy.

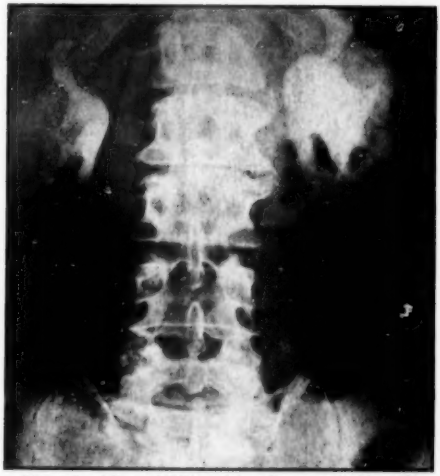

FIG. 6B (*Case* VIII).—Mr. D., aged 68. The same case ten days after operation.

FIG. 7A (*Case* X).—K. W. P., aged 57. I.V.P. at thirty minutes after injection, before prostatectomy.

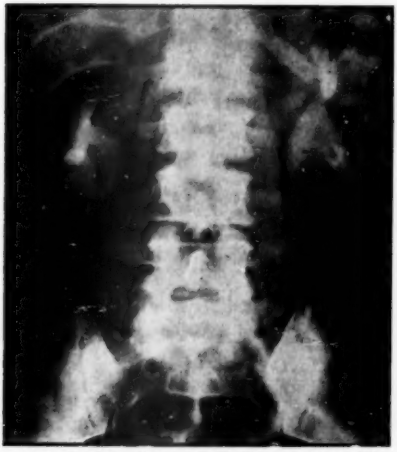

FIG. 7B (*Case* X).—K. W. P., aged 57. The same as 7A. Five weeks after operation.

I cannot better illustrate my point than by describing 3 of the most advanced cases of chronic retention with which we have dealt.

CASE XII.—C. W., aged 63, had had slight nocturnal incontinence for four years. His general condition was poor with urinary urea 0·9 grammes %, and blood urea 115 mg.%. The day after prostatectomy the blood urea rose to 150 mg.%. The following day it was back to 115 and the day after that down to 90 mg.%. One year after the operation the blood urea was stable at 57 mg.%, the urinary urea was unchanged and the kidneys just visible in i.v.p.

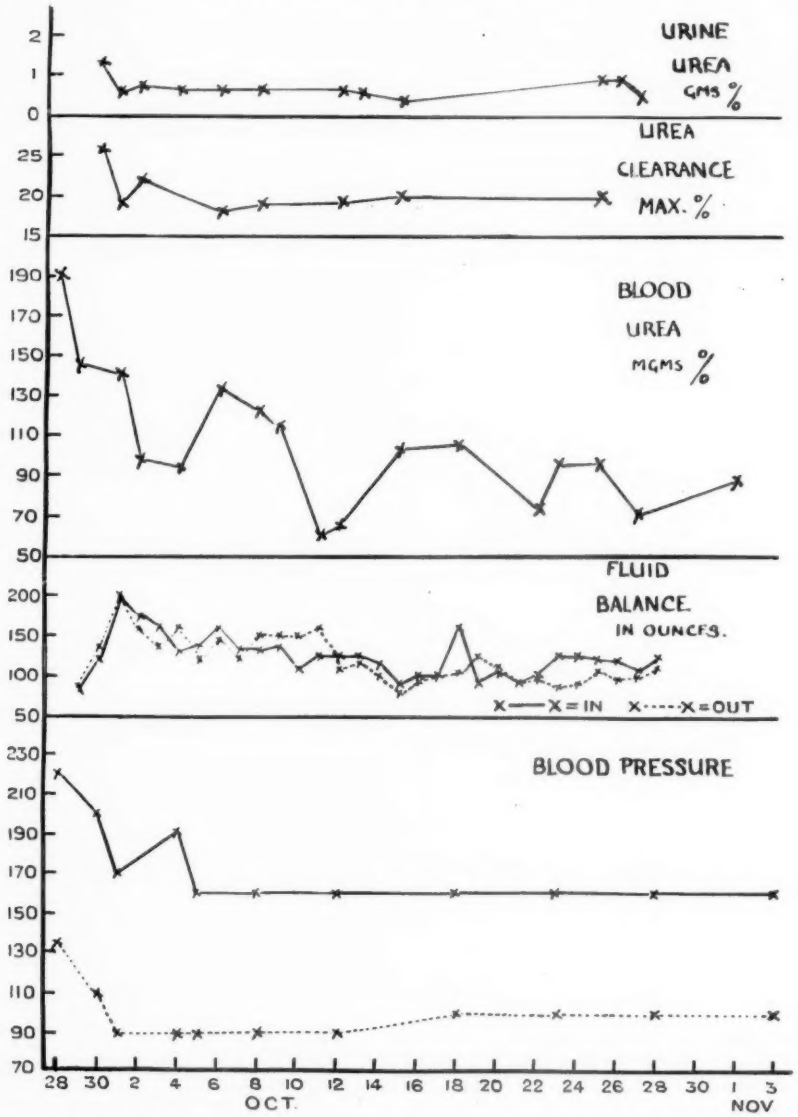

TABLE A (*Case* XIII).—J. B. N., aged 64. Note the rapid rate of fall of blood urea during the first forty-eight hours in association with forced fluids and free diuresis. The percentage urea in the urine remains steady throughout. This patient was able for discharge fourteen days after prostatectomy but was retained for further observations to be made.

CASE XIII.—J. B. N., aged 64, had had overflow incontinence and uræmic dyspepsia for one year. Before operation his blood urea was 190 mg.%, and the intravenous pyelogram showed no function at all. Prostatectomy was performed and the next day the blood urea was 146 mg.%. One year after prostatectomy the blood urea is stable at 100 mg.% with urinary urea 0·7 gramme%; no residual urine but a mild persistent *B. coli* infection. Almost nothing is visible in the i.v.p. but the patient is well and working (*see* Table A).

CASE XIV.—E. J. E., aged 78, had had overflow incontinence and generalized œdema for nine months. Vitamin-C deficiency and senile Parkinsonian tremor were manifest. Blood-urea levels immediately before and after prostatectomy (i.e. at an interval of only two hours) were 160 and 130 mg.% respectively. The intravenous pyelogram before operation showed no function. There was a greater urinary output than fluid intake in the post-operative period, the œdema disappearing rapidly. Six months after operation the blood urea was still 105 mg.%, but improved to 72 mg.% on increasing the daily fluid intake by three pints. There was a persistent infection with *B. pyocyaneus* (*see* Table B).

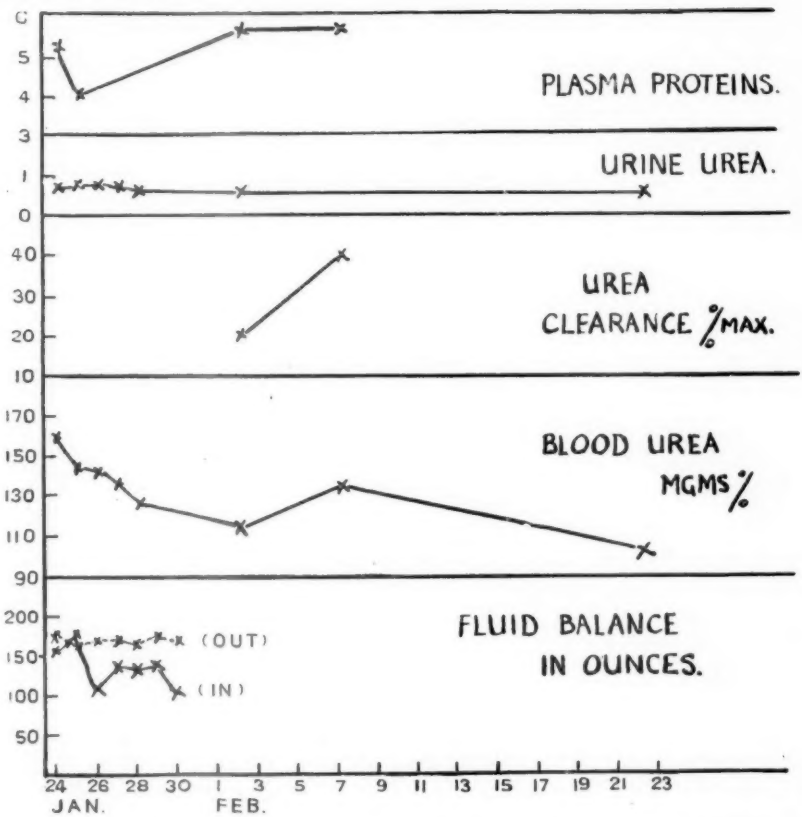

TABLE B (*Case* XIV).—E. J. E., aged 78. Note the rapid fall of blood urea in the first few days with free diuresis in marked excess over the fluid intake but associated with rapid disappearance of œdema.

It is important to realize that in these cases the improvement in the blood-urea levels, that is the relief of azotæmia, is due not to an improvement in renal function so much as to the fact that the urine can be got away. Once the obstruction is relieved it is possible to pass water through the kidneys almost as though they were simple dialysing membranes. The level of urinary urea does not rise during the period of observation. The clearance of waste products from the blood is effected by heavy diuresis.

The sensitivity of blood-urea readings to variations of fluid intake was well illustrated in a patient who had a nephrectomy for tuberculosis. The remaining ureter became obstructed and the ureterostomy was needed as a life-saving measure. This gave relief

only so long as a copious fluid intake was maintained. Shortening of the fluid intake was reflected within a few hours by a sharp rise in the blood urea.

The extent to which this diuresis needs to be pushed in prostatism has not been sufficiently realized hitherto. Once the obstruction has been relieved, provided the patient is not suffering from chronic interstitial nephritis, and provided that he has not got pyelonephritis, fluids can be given in almost unlimited quantities without any danger of drowning.

The amount of fluid required during the first few days in order to ensure a rapidly and steadily falling blood-urea level is so great that it cannot possibly all be taken by mouth, and intravenous therapy is an essential part of the management of these very severely damaged cases. Ten and eleven pints of fluid in twenty-four hours are the highest figures which we have hitherto given and it has been remarkable in the cases in which these large quantities have been prescribed to observe a fading away of existing œdema rather than an appearance of new œdema.

On the question of electrolyte balance, I will merely say that there is a risk both of giving too much sodium chloride and of giving too little sodium chloride. If too little is given a state of alkalosis appears and urea is retained in the circulation. If too much sodium chloride is given the kidney is unable to get rid of it, and large quantities of fluid are retained in the body as œdema in order to look after the excess of salt. It is indeed possible in these cases, we believe, to have œdema of the intercellular tissues with an excess of chloride, and at the same time to have dehydration of the cellular organs. This state of affairs exists because the total electrolyte content of the cell is stable and in order to remain in something like isotonicity with the surrounding tissues the cell has to give up fluid. (Compare the crenation of red blood cells when placed in hypertonic saline.) The clinical picture of this state is one of œdema with a dry rough skin and a dry mouth. In spite of the presence of œdema these patients are in urgent need of fluid which should be given in the form of 5 or 6% glucose. Another thing to remember is that in the presence of very heavy diuresis chlorides may be excreted from the body in large quantities. It is necessary, therefore, in the management of these patients to keep an eye upon the chloride level and this is most easily done by estimating the amount coming away in the urine by the simple drop technique of Fantus (1936.)

If the chloride situation is satisfactory, the governing factor in the amount of fluid required is the percentage of urea found in the urine. A simple mathematical equation will enable one to estimate the volume of urinary output required to get rid of the daily intake of protein, and at the same time to carry off a portion of the accumulated excess of nitrogenous waste products.

I have discussed three cardinal points in the maintenance of good renal function, namely the relief of obstruction, the control of infection and the supply of adequate fluid. There is one other factor of great importance. The blood supply to the kidney must be maintained at an adequate pressure. We have long suspected that a severe fall of blood pressure associated with the operation may interrupt the output of urine and that its re-establishment may take an appreciable time which the uræmic patient cannot afford. Whether or not this is true, we can at least demonstrate the effect of careful blood-pressure control during and after the operation.

Our anæsthetic technique is based on the desirability, indeed the absolute necessity as we think, for maintaining an even blood-pressure level. We do this by means of a continuous intravenous drip containing adrenaline in a solution of 1/250,000. By adjusting the rate of the drip it is possible to control the systolic blood pressure with a very considerable degree of nicety (*see Brit. J. Anaes.*, 1949, **21**, 182). Using this technique we have again and again demonstrated the continued excretion of indigo-carmine from the kidney during the operative procedure. In a series of 20 cases, there was little or no difference in the time taken for excretion of dye during operation, compared with the intervals observed before and after operation.

Since using this technique we have similarly observed repeatedly the output of very large quantities of water in the hours immediately following the operative interference. We have demonstrated that with careful management renal function is not interrupted by the operation and this is constantly reflected in the immediate post-operative fall in blood-urea levels when previously raised and the absence of any rise when previously normal.

The anæsthetist gives a spinal anæsthetic and in addition we like our patients to be asleep with a little pentothal. I have no doubt that there are other satisfactory anæsthetic combinations, but by employing the means I have described, viz. pentothal, spinal and adrenaline, we ensure a number of desiderata:

(1) We get complete relaxation. The spinal anæsthetic is controlled so as to extend to about the level of the umbilicus.

(2) We get a peaceful patient who is not worried by the operative procedure.
(3) We get a relatively dry field in spite of maintenance of a steady blood-pressure level.
(4) We have an anæsthetic which, once given, lasts for a couple of hours so that there is no need to hurry the operation and nothing to be gained by getting away quickly.
(5) The patient recovers consciousness and recovers the use of his legs in an orderly and gradual fashion with the minimum of excitability and post-operative disturbance.

What I have said really completes my case. We began this work with a view to finding out what happens in the patient with chronic retention who has his prostate removed. We started with certain preconceived notions which we were anxious to test. Our theories were:

(1) That renal failure due to obstruction could best be relieved by immediate and complete removal of that obstruction. All our observations have confirmed this belief. Incidentally, on opening the bladder we have often seen a deep flush over its whole surface and a readiness to bleed from the surface of the prostate. We have often seen fountains of water coming down the ureters, but we have never seen any blood come down them.

(2) That interruption of the favourable course of events after the relief of obstruction is due to some intervening cause of which sepsis is the most probable. This is a somewhat difficult thesis to substantiate beyond all question, but our experience with streptomycin in ascending pyelonephritis has satisfied us of the validity of the contention. An episode of low blood pressure is the second most probable cause.

(3) That given a known level of urinary urea and blood urea it should be possible to estimate the amount of fluid necessary to produce a steady improvement in the level of waste products in the blood. This we have found to be the case, and in studying this notion we have learned a great deal about the sort of care it is necessary to take in the management of the balance of fluid in these patients.

Certain other interesting points have emerged from our studies. We have now followed some of these patients for about two years. We have observed the steady improvement in their general condition and we have taken repeated samples of urine and repeated readings of blood pressure. We have satisfied ourselves that rapid and valuable recovery of renal function is possible in patients whom we would include in our middle group. It seems equally clear that those falling into the third group never recover concentrating power and depend entirely upon free diuresis for the adequate clearance of waste products from the blood-stream. In these cases, high blood-urea levels may persist for many months, but are compatible with a comfortable and useful life.

The urinary samples show us that the patients who leave hospital with a sterile urine remain sterile. Of the remainder who leave with infection, the infection persists in 4 out of 5 cases. In one case we have observed infection cause a gradual deterioration ending in death from insidious ascending urinary sepsis at the end of about a year. We think it probable that patients who show persistent sepsis three months or even less after prostatectomy should be readmitted to hospital, fully investigated, and subsequently treated by every known means with a view to clearing their urine.

In passing, and in regard to sepsis, we have reviewed our notes in order to clear up a point of doubt which is repeatedly arising in conversation, namely whether the patient with chronic retention is likely to have a sterile or an infected urine. A review of our cases has confirmed our contention that with very few exceptions the urine is sterile in chronic retention and in prostatics generally, unless there has been previous instrumentation. In relation to this point I would point out that we have not refused operative interference in any of our cases on account of previous catheterization although we deplore it and think it should be avoided whenever possible. The previously catheterized patients have certainly given us more trouble than the others. In this connexion I might mention the post-mortem findings in a patient with severe chronic retention who was cystoscoped for diagnostic purposes: he died from pyelonephritis within a few days of this simple examination. We have, during the period under review, seen more than one other case in which catheterization in chronic retention without any further interference has led to a fatal issue. It is our belief that these simple procedures are dangerous for the reason that the obstruction to the neck of the bladder is not removed and recurrence of retention with massive reflux up the ureters is a very likely sequel.

These last observations I have made as a reminder that the more conservative approach to these cases is not itself without danger. I am, however, fully aware that if the same rules of management which I have described are applied we may hope to see equally favourable improvements in the upper urinary tract following the relief of obstruction by other techniques than those I have described and with different timing. My purpose was not to discuss the technique of the operation, nor even to debate the relative merits of single versus staged procedures, but to describe the changes which ensue when obstruction has been relieved.

My last word but one has to do with blood-pressure levels. I came to this work with a preconceived notion that in chronic retention the blood pressure was raised and that following its relief the tendency was for the blood pressure to fall to a lower level. In the cases under review the results have been so capricious that I now feel at a loss to predict the change likely to occur. For every two that have gone down, one has gone up to a higher level (Table C).

TABLE C

		Blood pressure in mm.Hg		
No.*	Name	Before operation	On discharge or one month after operation	Six to eighteen months after operation
1	J. G. F.	120/80	180/90	220/120
2	J. B. N.	220/135	170/100	170/110
3	C. W.	230/130	140/85	170/100
4	J. W. B.	120/80	110/75	170/110
5	W. E. K.	200/100	170/90	250/90
6	K. W. P.	130/100	110/75	160/90
7	A. W. D.	150/70	120/80	150/80
8	E. T.	190/90	160/90	170/90
9	B. C.	140/80	120/80	160/70
10	L. W. D.	215/110	190/110	190/110
11	M. M.	220/110	190/100	190/110
12	J. J.	145/80	130/80	130/90
13	W. S.	170/110	140/100	200/120
14	C. W. H.	200/90	160/80	180/90
15	Mr. L.	170/100	120/70	140/80
16	C. C. W.	160/110	160/110	200/110
17	T. B.	260/145	200/120	Died
18	E. J. E.	240/130	200/110	220/90
19	H. O.	190/100	135/90	170/100
20	J. F.	200/100	180/90	140/90
21	J. M.	165/90	Died	—

* The case numbers in this Table do *not* accord with those given elsewhere in the text.

I must finish by sounding a note of warning for any who may feel disposed to take a more radical approach towards their prostatic problems. I believe there is one contra-indication which is likely to defeat the surgeon no matter what technique he employs. I speak of the arteriosclerotic patient who is incapable of co-operation. Any procedure which involves post-operative apparatus of any kind is likely to get us into trouble with cases of this character, and so far no one has devised any operation for the prostatic patient which does not involve some sort of apparatus. Probably transurethral resection most nearly approaches this ideal

Whatever is done, the operation is only a step in treatment. After-care, immediate and remote, is all-important and there is no field of work in which close attention to detail will prove more rewarding. Many workers such as Cook, Creevy, Lane, and D. K. Rose have kicked against the bogey of slow decompression. Wilson Hey has provoked us to further thought and further enquiry. I hope the studies here presented will be adjudged a useful and objective contribution.

Modern Drugs in Dental Surgery

By WALTER J. DILLING

Professor of Pharmacology and General Therapeutics, Liverpool University

IN order to review and assess adequately the values of modern drugs which have proved useful in dental surgery, it would be desirable to compare their efficiency with that of drugs formerly used for similar purposes. It would be impossible to do this in a short paper and even individual knowledge and experience would inevitably be called in question. It would be advantageous if concerted British dental authority could be obtained to jettison the useless or less efficient drugs in order to concentrate attention and critical clinical observation upon the more valuable dental medicaments. Such a selection of useful drugs for dental surgery should be based upon known pharmacological actions and practical clinical experience which do not always coincide. In making this plea, I include the necessity for a review of the many proprietary preparations which are provided sometimes for convenience in use and sometimes on dubious pharmacological grounds. Some thirteen years ago I condemned arsenic as a devitalizing agent and this produced private and public letters denouncing my ignorance ; yet I had suffered from its use personally three times. Again, iodoform still persists as an antiseptic ingredient of mummifying pastes and root-canal fillings, but upon no sound pharmacological foundation.

DENTAL ANTISEPTICS

At present, about 60 prevalent antiseptics would have to come under review, some prevalent merely because of attractive advertising. A generally useful series of dental antiseptics would doubtless include: hydrogen and zinc peroxides, sodium hypochlorite, iodine, formaldehyde and paraform, zinc sulphate, alcohol, phenol, cresol and a chlorocresol or chloroxylenol, clove oil, thymol, one surface-reducing agent, proflavine, gentian violet, sulpha drugs, penicillin and streptomycin.

Two recent additions to the *peroxides* merit comment. Zinc peroxide, a mixture of ZnO_2 (45%) with ZnO and Zn $(OH)_2$, evolves oxygen and leaves a residue of zinc hydroxide, which has useful antacid and astringent properties. Zinc peroxide, in powder, has proved a valuable application against anaerobic organisms in diabetic gangrene and as a paste in anaerobic gingival infections. Sodium percarbonate, Na_2CO_3, $1\frac{1}{2}H_2O_2$, on the other hand, leaves, on evolving its oxygen, the highly alkaline carbonate and from experimental tests by Dr. J. B. Roberts, in my department, it is unlikely to displace the less alkaline sodium perborate.

The detergent and antiseptic action of *surface-tension reducing agents*, such as hard soap is familiarly used in dentifrices, but fresh interest was aroused in this group by the slightly higher bactericidal efficiency and greater stability of *sodium ricinoleate* solutions which have a general, although not a specific, antiseptic applicability. Similarly irium, which is sodium lauryl sulphate, is another anionic detergent which has been much vaunted as an antiseptic in a dentifrice. It inhibits the Gram-positive, but not materially the Gram-negative, bacteria. It has the practical advantage for chalky districts that its calcium and magnesium salts are soluble, hence, added to ordinary soap, it retards the formation of insoluble calcium soaps. *Liquor sulphestolis*, or teepol, a solution of sodium secondary alkyl sulphates, has similar properties, and is effective in 0·5% solutions for cleansing surgical instruments.

Cetrimide, or *cetavlon*, is a cationic surface-reducing and bacteriostatic agent, consisting chiefly of trimethyl-cetyl-ammonium bromide, $C_{16}H_{33}(CH_3)_3N.Br$; it is not irritant or toxic to raw or mucous surfaces. It is highly effective in 1% aqueous solutions as a pre-operative detergent and antiseptic for the skin and wounds because the bacteriostatic effect lasts on the skin for some hours after it has dried. It is also useful for sterilizing instruments if 0·2% sodium nitrite is added to prevent rusting.

The *acridine dyes* are the most effective antiseptics against Gram-negative organisms; four are now available—acriflavine, proflavine hemisulphate or monohydrochloride, aminacrine hydrochloride and euflavine. For wounds, 0·1% solutions are used but, with prolonged use, they tend to delay healing. For oral infections 0·1% up to 1% aqueous, alcoholic or glycerin solutions are suitable as paints. Proflavine hemisulphate is most frequently used but aminacrine hydrochloride is less irritating, less staining and rather more efficient; these form neutral solutions (pH6) whereas that of acriflavine is acid (pH2).

Crystal or *gentian violet* (*Viola crystallina*) and *brilliant green* (*Viride nitens*), in 1% solutions as paints, have an effective toxicity for Gram-positive organisms, especially streptococci and staphylococci, and for the Gram-negative *Pseudomonas aeruginosa* (*Ps. pyocyanea*). Crystal violet is generally preferred and the tough superficial film which it forms is more resistant to bacterial invasion than that of tannic acid. The statement that it inhibits *Monilia* (*Candida*) *albicans* has been questioned by Seltzer and Bender (1949) who believe that 0·1% aqueous iodine is the only effective drug clinically for Monilia infections.

Ammonium and Urea Salts

Amongst recent remedies, mention should be made of the advocacy of ammonium salts with urea as oral antiseptics. The Groves (1934, 1935, 1942) announced that weak ammoniacal solutions had a solvent effect on mucin and plaques and reduced caries activity.

Kesel (1946–49) found that Lactobacilli disappeared from glucose cultures containing saliva from caries-immune cases and that the inhibitory substance was ammonia, possibly formed by antagonistic bacteria partly from urea and partly from breakdown of amino acids. Dibasic ammonium phosphate in 5% solution was considered a suitable ammonium salt to reduce the oral Lactobacilli and to be more efficient in the presence of urea. Urea it may be noted, is known to be a peptizing agent and a solvent of necrotic tissue, and it enhances the antiseptic action of sulphonamides and penicillin.

Henschel and Lieber (1949) evolved a dentifrice containing dibasic ammonium phosphate 5%, urea 22·5%, bentonite 5%, sodium lauryl sulphoacetate 3%, volatile oils 1%, saccharin sodium 0·3%, and precipitated calcium carbonate 63·2%, and they believe that it acts "by virtue of the protein denaturing action of the urea which combined with the ammonium phosphate produces a strong buffering action at the site of acid formation."

But this shotgun dentifrice does not lend itself to scientific assessment : Bentonite is a colloidal hydrated aluminium silicate which forms a colloidal gel and may have some adsorptive effect; the sodium lauryl sulpho-acetate is a surface-tension reducing antiseptic; and the volatile oils are also antiseptic.

While indicating a reduction of caries incidence by its use, Henschel and Lieber admit that some proportion of this may be attributed to enthusiastic use of the new dentifrice. The available clinical evidence is not convincing; and it may be recalled that Bruckner (1948) found that sodium bicarbonate as a dentifrice would lower the oral lactobacillary content.

Sulphonamides

The sulphonamides as bacteriostatic agents for oral infections have several defects. Their activity is impaired by pus, bacterial debris and products of tissue autolysis and also by substances containing *p*-amino-benzoic acid such as procaine, butacaine, benzocaine and orthocaine; further, the fact that, in order to displace *p*-amino-benzoic acid, they have to be maintained in considerable excess locally militates against their general utility for oral infections. They are bacteriostatic for Gram-positive organisms, hence for mixed infections S.P. powders (sulphathiazole 99%, proflavine 1%) are commonly used, or penicillin-sulphonamide powders (15,000 units per gramme of sulphathiazole): these are useful local applications in osteomyelitis, as adjuvants to surgical treatment and systemic bacteriostatic agents.

The earlier claims made for sulphonamides in Vincent's and other parodontal infections were unwarranted, and even sulphathiazole chewing gum, containing 0·25 gramme, has been shown to reduce chiefly the streptococcal flora of the mouth (Lewis and Burket, 1948). When, however, a tablet or a powder of sulphathiazole or a mixture of sulphanilamide and sulphathiazole ($\frac{1}{2}$ grain of each in a tablet) is placed in an extraction socket, there is reason from the greater local concentration to anticipate a favourable issue in the prevention of an infected socket (Krogh, 1948).

The systemic use of sulphonamides has been narrowed down to a choice between sulphathiazole, sulphadiazine, sulphadimidine (synonyms: sulphadimethyl-pyrimidine or sulphamezathine) and sulphamonomethyl-pyrimidine (synonym sulphamerazine). These are usually administered in a loading dose of 2 to 4 grammes, followed by 1 to 2 grammes at four hours or longer up to a maximum of 30 grammes. Sulphadimidine and sulphamerazine rarely cause nausea and give least risk of renal complications from crystallization of their acetyl derivatives which are fairly soluble. Being more slowly excreted, they may be given at six- or eight-hour intervals. In the unpredictable sensitive person, however, there is the possibility of skin sensitivity, aplastic anæmia, or agranulocytosis.

Sulphonamides systemically have achieved remarkably good results as a prophylactic against spread of infection in jaw injuries, alveolar abscess, cellulitis and osteomyelitis before and after operation, but resolution of local infections cannot be expected without surgical eradication of the infected focus—a fact that is sometimes overlooked by medical practitioners.

Penicillin

Five penicillins are now known, differing in their side chains: Pentenyl-penicillin (I or F), benzyl-penicillin (II or G), hydroxybenzyl-penicillin (III or X), amyl-penicillin (dihydro-F) and heptyl-penicillin (IV or K), the last of which is much less effective. The standard is penicillin II or G. In this country, penicillin is used as the sodium or calcium salt but in America the less hygroscopic potassium salt is commonly employed. This is now being made in Britain.

The *mode of action* of penicillin is probably to interfere with amino-acid metabolism by preventing the passage of glutamic acid through the bacterial membrane. It is bacteriostatic, or, in sufficient concentrations, bactericidal, and acts on dividing, but not on resting, organisms. Its activity is not impaired by pus or bacterial debris, but it is inactivated by acids and by the enzyme, penicillinase, formed by *Esch. coli* and *B. subtilis*, and other organisms.

It is effective mainly against Gram-positive organisms, but the individual sensitivity of organisms varies greatly.

Organisms Affected

The majority of indigenous and casual oral organisms are sensitive to penicillin, including *Actinomyces bovis*, *Borrelia* (*Spironema*) *vincentii*, *Fusiformis dentium* (*B. fusiformis*) and *Lactobacillus acidophilus*, although these have a relatively higher and variable resistance. Insensitive to penicillin are the Gram-negative: *Hæmophilus influenzæ*, *Klebsiella pneumoniæ* (Friedländer's B), *Pseudomonas aeruginosa* (*Ps. pyocyanea*), *Aerobacter aerogenes*, and the yeast *Monilia* (*Candida*) *albicans*.

The action of penicillin is not immediate and this presents dental problems for the maintenance of its local activity. MacGregor and Long (1945) reported that the effect of penicillin, whether used locally or systemically by injection, on the oral bacterial flora was at first a rapid fall in the numbers of sensitive organisms, succeeded after about three days by a secondary phase of invasion by insensitive Gram-negative organisms of the Bacterium group, which by producing penicillinase, impaired the efficiency of the penicillin, and thus enabled the former Gram-positive organisms to return (Long, 1947).

Recent American experiments have been directed to discovering the effect of penicillin on the Lactobacillus, but the results obtained, having regard to the wide natural variations in the oral bacterial flora, are certainly inconclusive. A variable reduction in Lactobacilli —as well as in more sensitive organisms—has been demonstrated associated with increases in the numbers of Escherichiæ and Aerobacteriæ, but there is no unequivocal evidence of a striking or even significant reduction of Lactobacilli by penicillin in lozenges, chewing gum or tooth powders, nor acceptable evidence of control of caries by its use (Hill and Kniesner, 1949; Hill, Kniesner and White, 1949; Slanetz and Brown, 1949; cf. Hill, 1948).

Methods of Employment

Calcium penicillin cones or tablets (1,000 to 15,000 units) some of which also contain ½ grain each of sulphathiazole and sulphanilamide, have proved effective in the prophylaxis and treatment of septic sockets; dusting powders of similar composition are valuable locally in osteomyelitis and periostitis after operation. The considerable retarding effect of penicillin on blood coagulation and clot contraction, recorded by Fleming and Fish (1947) must here be recalled. This defect can now be overcome by inserting the penicillin tablet or cone, and spraying or painting the extraction wound with thrombin solution (5 units per ml.) ; the thrombin annuls the penicillin's anticoagulant action without impairing its bacteriostatic powers (Peter and Little, 1948).

Infected root-canals were treated with penicillin initially by irrigation, sealing, or points impregnated with solutions of 5,000 to 20,000 units per ml., but with uncertain results. A meticulous determination by Stewart (1948) of the capacities of root-canals showed volumes in incisors of about 0·01 c.c., for canines and premolars of about 0·02 c.c. and for molars about 0·035 c.c., hence of a 10,000 units penicillin solution per ml. only from 100 to 350 units would be available in the canal; also an aqueous solution of sodium penicillin is absorbed from the canal in twenty-four hours. By the use of suspensions of 600,000 units of calcium penicillin per ml. of arachis oil, a potential root-canal content of 6,000 to 20,000 units can be gained and sterility can usually be attained after one application; the oily suspension remains active for at least a week. Failure may, of course, occur if penicillin-resistant organisms are present (Grossman, 1948; Grossman and Stewart, 1949; cf. Buchbinder and Schwartz, 1948).

Systemic penicillin, when injected as the aqueous solution, *injectio penicillini* (50,000 units per ml.), is excreted rapidly by the renal tubular epithelium; three-hourly injections were first employed; now, with adequate supplies it may be injected in doses of 100,000 to 500,000 units thrice to once daily respectively. Delayed absorption is achieved by the use of *injectio penicillini oleosa* (calcium penicillin with 4·5% white beeswax in arachis oil or ethyl oleate) containing 125,000 units or more per ml.; of this, 300,000 units in twelve, or 600,000 units in twenty-four, hours is desirable. Delayed absorption is also gained from the less soluble procaine-penicillin—a suspension of penicillin (300,000 units) with 0·12 gramme procaine and 2% aluminium stearate in 1 ml. of arachis or sesame oil. This gives an initial blood-serum level of 0·2 units per ml. for one to three hours and levels of 0·06 unit per ml. for forty-eight hours; thus one daily injection of 1 ml. is usually sufficient, and with it skin reactions and local pain are less frequent.

A more recent preparation, penicillin S-R (soluble and repository) contains, suspended in water, 400,000 units per ml., of which 300,000 units are insoluble procaine-penicillin and 100,000 units soluble penicillin. This is stated to give a high blood percentage (4 units per ml.) within thirty minutes, and not less than 0·1 unit per ml. during twenty-four hours.

Oral administration of penicillin is now practicable, but becomes expensive because the dose must be about five to ten times that by intramuscular injection as only about one-third is absorbed. Penicillin is destroyed by the gastric acidity, but, beyond that, is readily absorbed in the small intestine. It is best given in 4 fl. oz. (130 ml.) of a 5 or 10% glucose solution containing as buffers, 1 gramme (15 grains) of sodium bicarbonate or 0·5 gramme (8 grains) sodium citrate per 20,000 units. For adults the dosage would range between 100,000 to 200,000 units three-hourly, hence this mode of administration is generally reserved for children to whom 3,000 units per kg. (or 1,400 units per lb.) body-weight is given.

A systemic penicillin "umbrella" is very desirable, if not essential, before and after multiple extractions of teeth with parodontal or apical infection. It involves the injection of 50,000 to 100,000 units of aqueous penicillin an hour or so before operation to gain a rapid peak, and further similar doses at three and six hours afterwards, with possibly a dose next day; or a single injection of procaine-penicillin (300,000 units) one or two hours before extraction. The gain for the patient is decreased inflammatory œdema and post-operative pain, while the rapid healthy granulation and healing are remarkable; there is also a secure insurance against the development of a bacteriæmia, particularly of a subacute bacterial endocarditis (*cf.* Ostrander, 1948); and, for all cases of cardiac disease, it should be a routine even when healthy teeth are to be extracted.

Systemic penicillin should be given prophylactically before, and continued during, local surgical treatment of jaw fractures, apical abscesses, osteomyelitis, periostitis, cellulitis, acute and chronic pericoronal infections, maxillary sinusitis and gangrenous stomatitis (cancrum oris). Its use in such cases prior to surgical measures, or the topical application of penicillin or sulphathiazole to any infected area, should always be considered because, although it will not usually eradicate the infective focus, it will mitigate the local inflammatory reaction and render surgical extirpation of the infected focus less hazardous. Penicillin should never be used as a substitute for surgical treatment of localized sepsis but it enhances the effectiveness of the protective shield of phagocytes against the spread of the local invasion.

In Vincent's infection, particularly at the acute stage, systemic penicillin will materially assist the efficiency of local treatment (Rankow, 1949).

In actinomycosis, as MacGregor (1945) noted, the response to penicillin varies, as strains differ in susceptibility; more recently, Nichols and Herrell (1948) found that by extending treatment over four weeks, penicillin proved an effective therapeutic agent.

Toxic effects from penicillin are practically absent, except that allergic reactions, usually from sensitization by a previous dosage may produce itching erythematous eruptions, muscular and joint pains with stiffness and even asthmatic attacks. These may call for relief by antihistamine drugs orally, such as anthisan (or neoantergan maleate) 50 to 100 mg.

(¾ to 1½ grains) in tablets; benadryl 25 to 100 mg. (2/5 to 1½ grains) in capsules; or antistin 100 to 200 mg. (1½ to 3 grains) in tablets; and for the asthma, theamin (or theophylline monoethanolamine) 0·1 to 0·18 gramme (1½ to 3 grains) in capsules twice or thrice daily is effective; it is also available with amytal as a sedative for nervous patients. The itching is best controlled by a cooling spirit lotion.

Streptomycin

Streptomycin, an antibacterial agent from *Streptomyces griseus*, forms a crystalline base, which is used as the very soluble hydrochloride, sulphate, or calcium chloride double salt. As a mixture of the latter two would precipitate calcium sulphate, a change from one to the other should be avoided or separated by several weeks' interval. Streptomycin is fairly stable below 15° C. but solutions are best freshly prepared.

Dose: by *intramuscular injection* daily 1 to 2 grammes (15 to 30 grains) or up to 20 mg. (1/3 grain) per lb. body-weight in 10 or 20% solution in sterile water or saline.

Streptomycin is bactericidal against many penicillin-resistant species including *Proteus vulgaris*, *Klebsiella pneumoniæ* (Friedländer's B.), *Escherichia coli* (*B. coli*), *Hæmophilus influenzæ*, *Pseudomonas aeruginosa* (*Ps. pyocyanea*), *Brucella abortus*, *Eberthella typhosa* (*B. typhosus*), *Pasteurella tularensis*, and *Mycobacterium tuberculosis*; but resistant strains are liable to develop during treatment.

Taken orally, little is absorbed, but it has been used with favourable results before colonic operations and for infantile gastro-enteritis.

Given intramuscularly, the maximal blood level occurs within one to three hours, decreasing by renal excretion during the ensuing ten to twelve hours. Two injections of 0·5 gramme (8 grains) daily are now regarded as adequate, except in tuberculous meningitis.

Streptomycin has proved effective in bacteriæmia from *Esch. coli* and *Pseudomonas aeruginosa*; in pulmonary infections from *Klebsiella pneumoniæ*, in bacilluria from *Proteus vulgaris*, *Streptococcus fæcalis*, *Esch. coli*, and *Ps. aeruginosa*; in peritonitis, in tularæmia and in meningitis from *Hæmophilus influenzæ*.

It is the most effective drug for miliary and meningeal tuberculosis, but is often only a palliative. Its action is slow and one or two months' treatment is usually advised; even then, its effect may be only arrestive.

Resistant strains of the sensitive organisms may develop rapidly, especially in urinary infections where brief intensive treatment (3 grammes daily in 4 doses) for two to three days is used. In tuberculous infections, resistant strains do not usually appear before the fifty-third day of treatment, but, when developed, remain permanently. These resistant strains limit the duration of an effective dosage and may prevent its useful repetition, while cases with positive sputum will disseminate resistant strains.

In pulmonary tuberculosis, streptomycin should be reserved for recent and progressive lesions which are unlikely to improve on bed-rest, collapse therapy or thoracic surgery; for acute spreads after collapse therapy or operations; and for rapidly advancing cases for which collapse therapy or operative treatment is inadvisable. Streptomycin may so improve the patient's resistance and condition that collapse therapy or thoracic surgery becomes practicable, especially under its protective influence. Tracheal and bronchial lesions respond well; intestinal and peritoneal cases improve but commonly relapse; and in renal tuberculosis, temporary arrest may be obtained. One case of cure of tuberculosis of the tongue has been recorded (Wolfer *et al.*, 1948). It cannot replace surgery in joint or bone tuberculosis.

Dihydro-streptomycin sulphate (Dose: intramuscularly, 1 to 3 grammes (15 to 45 grains) daily; or intrathecally, 0·05 to 0·1 gramme (¾ to 1½ grains) is equal in therapeutic activity to streptomycin and is less liable to produce toxic effects.

Streptomycin has proved effective in root-canal therapy. Absorbent points impregnated with 1 mg. (1/60 grain) of streptomycin and dried were found to eradicate penicillin-resistant organisms, and to maintain an antiseptic efficiency for two weeks (Bartels and Buchbinder, 1949; Keefer *et al.*, 1946).

An oily suspension is more satisfactory and keeps better than an aqueous solution. Grossmann and Stewart (1949) advise a streptomycin-penicillin suspension containing 500,000 units of each in 1 ml. of oil made with potassium penicillin II and streptomycin calcium chloride (0·5 gramme—not the sulphate which is incompatible with penicillin). Root-canals treated with this and sealed with gutta-percha and externally with zinc cement were found sterile in two-thirds of cases after one treatment and in nearly all cases after two treatments. (*Note*: Zinc cements tend to decompose both penicillin and streptomycin).

Toxic effects from streptomycin are seldom troublesome with 1 gramme dosage daily and have declined with the advent of purer products. Headache, skin flushing, faintness and nausea, relievable by antihistamine drugs may occur. Tinnitus, vertigo and deafness from vestibular dysfunction may be transient or persistent, and form a risk in treating meningitis.

Other Antibiotics

Para-aminosalicylic acid (P.A.S.) or paramisan is used as its sodium salt which forms a soluble crystalline di-hydrate and is available as a sterile 20% solution in 10 ml. ampoules. It is bacteriostatic against *Myco. tuberculosis in vitro*; its action is not impaired by serum, and resistant types do not appear to develop. The sodium salt is given orally in amounts of 12 to 20 grammes (180 to 300 grains) daily in divided doses—commonly 3 grammes (45 grains) at two and a half or three hourly intervals for three or six months. It is absorbed rapidly and one hour after a dose the blood level is about 7 mg. per 100 ml. ; but it falls rapidly to almost nil in three hours as renal excretion is rapid. It is not toxic but is unpleasant to take, and may cause nausea and diarrhœa.

Para-aminosalicylic acid seems likely to be beneficial in conjunction with sanatorium treatment for recent acute exudative types of pulmonary tuberculosis by promoting fibrosis of the lesion; also 10 and 20% solutions applied locally have produced very good results in tuberculosis of the skin and of the tongue; such solutions in 2 ml. doses have also been injected into cavities with benefit. Its therapeutic field cannot be fairly defined at the moment but it is unlikely to displace streptomycin. One important point has emerged recently, namely that para-aminosalicylic acid, given in conjunction with streptomycin, appears to delay or prevent the appearance of streptomycin-resistant strains of the tubercle bacillus. On this line of advance, patients are now undergoing controlled treatment and we must await the results.

Aureomycin or *Duomycin*, obtained from *Streptomyces aureofaciens*, is used as a yellow, crystalline, soluble hydrochloride, and given orally in 0·6 to 3·5 grammes (10 to 50 grains) doses daily in four portions (or 10 to 60 mg. per kg. (1/15 to 2/5 grain per lb.) bodyweight); or intramuscularly, 10 to 20 mg. (1/6 to 1/3 grain) daily in sterile saline. It is bacteriostatic, rather than bactericidal, towards both Gram-positive and Gram-negative organisms, and has a wider range than streptomycin, including the Brucellas, Rickettsias and certain virus diseases, e.g. psittacosis and lymphogranuloma. It has given very favourable results in brucellosis, typhoid, typhus and Rocky Mountain fevers, in urinary infections with *Esch. coli* and in syphilis (Willcox, 1949). Side actions are transitory nausea, vomiting and diarrhœa.

Aureomycin—0·25 gramme (4 grains) orally in capsules every four hours during the day —has produced rapid reduction of temperature, pain and symptoms in a variety of oral infections such as stomatitis, gingivitis, pericoronitis, submaxillary adenitis and chronic diffuse osteomyelitis (Jacobs and Jacobs, 1949). Acute ulcerative and necrosing gingivitis, predominantly from Vincent's infection, is also favourably influenced (Goldman and Bloom, 1949), but these are preliminary reports of which confirmation is desirable. Aureomycin borate in 0·5 to 1% solution is not irritant and may prove useful locally.

Chloromycetin, or *Chloro-amphenicol*, obtained from *Streptomyces venezuelæ*, or prepared synthetically, has been used in doses of 2 to 4 grammes (30 to 60 grains) initially and 0·25 gramme (4 grains) for maintenance at two-hourly intervals for similar purposes to aureomycin but I have no records of its use in oral infections.

Tyrothricin, an antibiotic from *Bacillus brevis* and effective against Gram-positive organisms, is supplied as a 2% solution in alcohol; tyrothricin is insoluble in water but the alcoholic solution, when added to water, forms a colloidal suspension. For clinical use 1 ml. of the alcoholic solution of tyrothricin is diluted with 60 ml. of distilled water; this is not irritant or toxic, and has been widely used as an antiseptic lotion for wounds. In strength of 1 : 5,000 (i.e. 1 ml. of the 2% alcoholic solution added to 100 ml. of water) it has been useful when instilled into the infected maxillary antrum. Recently, lozenges containing 1 mg. of tyrothricin with 5 mg. of benzocaine have been introduced for oral and throat infections.

Obtundents

A review of opinions on the obtundents seems necessary in view of the result of work with radio-phosphorus. The majority of obtundents have hitherto been thought to coagulate the contents of the dentinal tubules and thus to decrease their permeability; but, after treating cavities in dogs' teeth with phenol, phenol followed by alcohol, fluorides, or silver nitrate followed by eugenol, and then with a radio-phosphorus isotope—in solution as disodium hydrogen phosphate (P^{32})—for forty-five hours under an amalgam filling, Amler (1948) found that there was increased permeability of the radio-phosphorus into the tubules. On the other hand, the radio-phosphorus did not penetrate a layer of zinc oxyphosphate cement.

Manley and Hardwick (1948) have pointed out that, as the vital dentinal tubules are dependant on the pulp, devitalizing chemicals applied to desensitize the peripheral endings of the tubules may, by penetration, damage the odontoblast layer and induce a pulp reaction.

They regard silver nitrate as being the least risky because it is precipitated as chloride or phosphate; and zinc chloride and formaldehyde as reasonably safe. Sodium fluoride, 33%, although it acted rapidly in an experimental case, produced gross inflammatory lesions of the pulp. Care has commonly been enjoined in regard to the use of the more caustic and penetrating obtundents; but these results suggest that experimental work on similar lines on the effects of eugenol and thymol in experimental cavities would yield helpful information.

Control of Hæmorrhage

The value of drugs in accelerating clotting has always been difficult to assess and all have had their disappointments with metallic and vegetable astringents, with calcium therapy and with hæmostatic sera. There are now available satisfactory preparations from human blood, and substitutes for these.

Human thrombin is a cream-coloured powder, forming an opalescent solution in normal saline (1 unit clots 1 ml. of a 0·1% fibrinogen solution in fifteen seconds). It is issued in containers holding 50 and 500 units. Solutions of human thrombin from 5 to 30 and 50 units per ml. in saline may be applied or sprayed on bleeding surfaces; but they are more commonly used soaked into fibrin foam, which is then applied to the bleeding point, when clotting takes place immediately. Thrombin may be used to annul the anticoagulant effect of penicillin. Bovine thrombin (200 units per ml.) has also been used locally.

Human fibrinogen is a white powder, soluble in normal saline, but, from this, fibrin deposits slowly; hence solutions are prepared immediately before use. Fibrinogen is used as a 1 or 2% solution, along with thrombin to promote its clotting, in order to cause the adhesion of skin grafts or—although less satisfactorily—of mucous membrane grafts, and to fix nerve sutures; the clot strength depending on the fibrinogen concentration. Fibrinogen is also injected intravenously (10 ml. of a 2% solution) to reduce the clotting time in hæmophilia; the effect lasts for twenty-four to thirty-six hours.

Fibrin foam (*human*) is made by adding thrombin to a foamed 1% solution of fibrinogen and forms a light white spongy material, or, as fibrin film, a thin transparent sheet. Suitable portions are soaked in thrombin solution, and placed on the bleeding point. Blood coagulation occurs at once and the fibrin is left in position to be absorbed.

Fibrin foam with thrombin has been used successfully in controlling hæmorrhage from sockets, but in hæmophiliacs, reliance should not be placed on purely local measures (Henry, 1947). For antiseptic purposes, there may be incorporated with the thrombin solution, penicillin or tyrothricin.

Gelatin sponge or "gelfoam" is a water-insoluble gelatin foam, used in the same way as fibrin foam, with or without thrombin, and it is well tolerated by the tissues (Gwinn *et al.*, 1948). It has also been used soaked in bovine thrombin (200 units per ml.) containing 200,000 units of penicillin and has proved an effective hæmostatic for primary and secondary hæmorrhage in extraction wounds (Silverman, 1949).

Oxidized cellulose or "oxycel" is prepared by nitrogen dioxide oxidation of cellulose into cellulosic acid. It has a pH of 4, and inactivates thrombin and also penicillin, unless it is first immersed in 1% sodium bicarbonate, but this tends to weaken the strength of the cellulose. It is effective without thrombin and is said to form a coagulum of salts of cellulosic acid with hæmoglobin. It is used, after dipping in sulphathiazole powder, as a plug.

Sodium alginate is obtained from the Laminaria seaweed and is a white or yellowish powder which slowly forms a viscous solution in water. When applied in 1% solution to raw tissues, it is precipitated as calcium alginate which acts as a hæmostatic and is later absorbed. Gauze impregnated with the powder may be applied to the bleeding area or a solution of the powder applied on gauze and then sprayed with an isotonic solution (2·5%) of hydrated calcium chloride. Absorbable surgical gauzes and wools are available made from calcium alginate fibres.

More critical clinical experience than is available at present will be necessary to convince me that these substitutes for the blood proteins have a direct hæmostatic action when used without thrombin. They do, however, provide an absorbable skeleton mesh on which clotting is facilitated.

Hyaluronidase

The *mucolytic enzyme, hyaluronidase*, which has recently become available under the name "hyalase", may have dental applications. Hyaluronic acid, a mucopolysaccharide forming viscous solutions, is considered to be the tissue-cement substance. It is polymerized and its viscosity greatly reduced by the enzyme hyaluronidase, which has been called the "spreading factor" for injected fluids. When fluids are injected under its influence, they diffuse rapidly into the surrounding tissues without causing local swelling. The usual dose is 1 mg. (1,000 units) of the powder dissolved in 1 ml. of sterile water, freshly prepared, and it is injected into the tube conducting the fluid for subcutaneous infusion.

Hyaluronidase has been used to increase the area rendered anæsthetic by procaine to almost double. To 50 ml. of a 1% procaine, 0·8 to 1·6 mg. of hyaluronidase was added, along with 0·5 ml. of 1 : 1,000 adrenaline in some cases. Although it increases the area of anæsthesia—more so with adrenaline—it shortens the duration because of quicker absorption. Within five minutes of its injection, without adrenaline, the area which corresponds with the anæsthetized zone becomes erythematous; with adrenaline, the area is blanched. Some tenderness in the area may be felt (Looby and Kirby, 1949).

It has also been suggested that the destruction of interfibrillary cement substance in parodontal disease may be due to hyaluronidase formed by the bacteria in pyorrhœal pockets (Goldsmith, 1949).

Dr. Alexander MacGregor agreed entirely with Professor Dilling's suggestion for discarding those drugs which had become redundant. Thus, the use of tricresol in pulp canals, still continued, had been shown to be harmful in many cases. Iodoform which had long been discarded in general surgery was still very frequently employed, and there were other and better antiseptics. Iodine was used for painting on to the mucous membrane immediately before local injections though it was known that it took some considerable time to exert any action. The use of sulphonamide powders in sockets and the use of solid sulphonamide or penicillin cones frequently gave rise to trouble for mechanical reasons in hindering the clotting of blood. Professor Dilling mentioned the use of injections of penicillin in Vincent's infection. Heavy doses of at least half a million units had to be given to affect the oral flora. The speaker still preferred local treatment with penicillin pastilles, but stressed the better results obtained with a gelatin base. Professor Dilling had rightly drawn attention to the dangers of the empirical use of penicillin, the abolition of penicillin-sensitive organisms allowing relatively insensitive types to multiply, these organisms liberating penicillinase which destroyed the penicillin and allowed a return of the original infecting organisms. The speaker entirely agreed that the evidence that the presence of the ammonium ion was the best or only factor in inhibiting the Lactobacillus should be treated with reserve as it was known that many other substances would inhibit the growth of this organism. Further evidence was needed in addition that the Lactobacillus had anything to do with the causation of dental caries.

President—W. N. GOLDSMITH, M.D., F.R.C.P.

[*October* 20, 1949]

Familial Benign Chronic Pemphigus (Hailey-Hailey).—R. B. COLES, M.R.C.P. (for SYDNEY THOMSON, M.D.).

Miss C. S., aged 34; occupation, milliner.

History.—Onset of skin trouble on back of neck and thighs five years ago (i.e. at 29 years). At first these patches did not bother her much ; they waxed and waned in extent and severity and occasionally disappeared. Decided worsening occurred in hot weather.

Deterioration in the condition of the groins and neck followed an attack of bronchitis in January 1949 (this was treated with penicillin). Three months later lesions appeared in the armpits and antecubital fossæ. She was admitted to hospital on June 24, 1949.

Condition on admission.—Skin: Lesions were present on the sides of the neck, the axillæ and groins, and the antecubital fossæ. Detailed examination revealed erythematous patches covered with moist scales, and showing marked fissuring. The raw red base of the lesions could be seen in the depth of the fissures. The scaling at the edges suggested fused, flaccid bullæ, but no fluid-containing lesion has been seen in this case. This undermined epithelial border spread peripherally and showed circinate configuration, particularly at the sides of the neck.

Nikolski's sign negative.

General physical examination revealed no abnormality.

Present condition.—Slight residual lesion on left at the back of the neck. Axillæ much improved, lesions paler and much flatter. Antecubital fossæ clear. Groins are still hyperæmic and have improved less than the other regions.

Family history.—The patient is one of a family of nine, five of whom (two sisters and three brothers) are said to have the same condition. Her eldest sister, aged 40, has been examined by us. She had similar lesions in the same sites as this patient and a true bullous fringe at the edge of the lesions in the left axilla.

Treatment has included fractional doses of X-rays to the groins, a course of aureomycin and a small blood transfusion.

Investigations.—W.B.C. 8,500 per c.mm. (neutros. 66%, eosinos. 9%, lymphos. 22%, monos. 3%).

Potassium iodide patch tests negative.

Fungus: None seen on direct examination of several specimens of skin; none cultured.

Biopsy from left antecubital fossa (Dr. C. F. M. Hall).—Section shows moderate acanthosis and a little patchy parakeratosis. There is a well-marked dyskeratosis with acantholysis, the clefts tending to run both horizontally and vertically. The cells around the edges of the clefts show shrinkage and there are very occasional lymphocytes and polymorphs in the acantholytic area. The superficial corium also shows a little infiltration by lymphocytes and polymorphs, mainly focal.

Conclusion.—The appearances are compatible with those described in benign familial dyskeratosis (Hailey-Hailey syndrome).

Comment.—We regard this as a typical case of Hailey and Hailey disease. The history of attacks and remissions, the age at onset and all the clinical and histological features resemble those described in the literature. The apparent high family incidence of the condition is of interest. Here, 8 out of 18 individuals in three generations may be affected. Becker and Obermayer mention 27 cases out of 78 in three generations and this high case incidence in affected families seems to be a common feature, although isolated cases are described. It is also interesting that in this family the males are troubled principally by eruptions on the neck; perhaps this is related to collar-wearing.

Another feature of this case is the worsening which occurs in hot weather. Furthermore, we are told that two of her brothers have had attacks for the first time in this year's hot summer. It seems possible then that heat may be a precipitating factor in some cases of the disease.

Chronic Benign Familial Pemphigus (Hailey-Hailey).—STEPHEN GOLD, M.R.C.P.

Mr. W. R., aged 69, reported to St. John's Hospital in June 1949 complaining of an irritable rash on the back of the neck, cheeks and chin. He said that it had first started when he was 40, was generally confined to the hairy areas and was entirely dependent on temperature. He was not affected in the winter and the rash would appear after the first hot, sunny day. No treatment had been of any avail and greases tended to make it worse.

He described the initial lesions as blisters, sometimes as large as a pea, which would occur on the friction area at the back of the neck, the penis and scrotum and occasionally on the backs of the fingers and on the dorsal surfaces of the toes. As the blisters developed, itching was intense. Once they had been ruptured after scratching, the irritation was relieved. A clear fluid would exude on rupture of the blisters and a crust would form. The crusts would fall off after some days and no scarring would result.

On examination the only lesions of importance were on the back of the neck. They appeared as superficial, crusted lesions which were grouped in almost herpetic fashion. A few small blisters were also present. There was no Nikolski's sign.

Family history (*see* Fig. 1) reveals that the patient's mother suffered from the same condition involving the back of the neck. Two of his sisters are also affected, with particular involvement of the axillæ and perinea. The patient's daughter suffers from pea-sized blisters on the legs, axillæ and perineum.

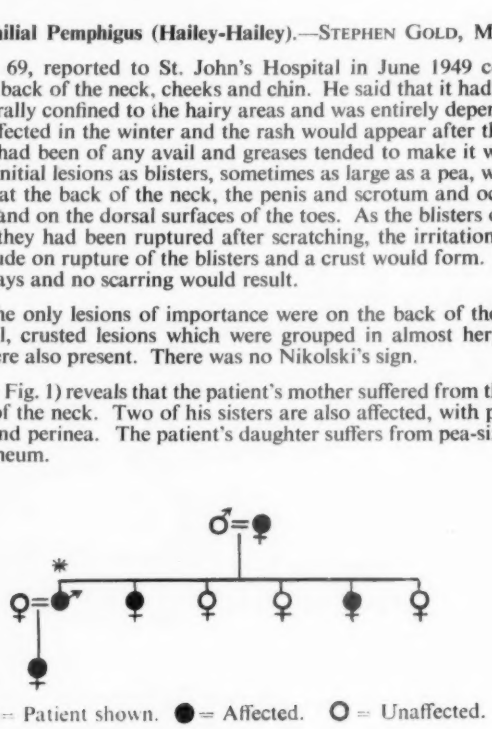

FIG. 1.

Treatment given over varying periods included sulphadiazine by mouth and later vitamin A. Local applications were not well tolerated on the whole. The lesions cleared with the onset of the cooler weather; but before this some developed on the temples for the first time. It seems that more sites are becoming susceptible to the blistering process

[Slides were on view.]

Benign Pemphigus.—R. J. CAIRNS, M.R.C.P. (for G. B. MITCHELL-HEGGS, O.B.E., F.R.C.P.)

Mr. S. K., aged 41, a Pole.

Nine years ago small bullæ occurred over the presternal region and were followed a year later by similar lesions on the sides of the neck. Four years ago the axillæ and groins were affected and two years later the occipital region. There has been no seasonal variation, nor has there been any involvement of mucous membrane. From January to June this year (1949) the skin was almost clear.

Family history.—No history of similar disorders.

On examination.—The scalp is clear. There are brown, pigmented macules on both sides of the neck. At the apex of each axilla the skin is moist and macerated with fine fissuring, and surrounding this area there is brown pigmentation of arciform outline and scattered bullæ up to 1 cm. in diameter. The skin of the groins, scrotum, perianal and internatal regions is slightly vegetative and sodden. The feet show mild interdigital scaling from which fungus has been isolated. Nikolski's sign is negative.

Investigations.—Blood count normal. W.R. and Kahn negative.

Histology (Dr. L. Crome).—"There is hyperkeratosis but no parakeratosis and the stratum granulosum is not well marked. The malpighian layer is thin in places and normal in others ; there is no acanthosis. Many cells in the malpighian layer show hydropic change and, in addition, there are numerous empty spaces in it. These spaces, which were probably filled with fluid, are situated in the stratum spinosum, being separated from the papillary layer by a single layer of basal cells. The papillæ are often elongated and project in a finger-like fashion into the bullæ. The basal cells contain a moderate amount of melanin. There is very little inflammatory change in the corium and the amount and distribution of elastic tissue are within normal limits.

"The above changes resemble those described by Hailey and Hailey in benign pemphigus."

Tzanck test: Smear from the blister contents shows dyskeratotic cells.

Progress.—After three days' sulphapyridine therapy, the lesions became more itchy and new blisters appeared.

Present treatment.—Vit. A 100,000 i.u. daily. Lot. plumbi and glycerin topically.

Familial Benign Pemphigus.—R. J. CAIRNS, M.R.C.P. (for I. MUENDE, M.R.C.P.)

Mrs. K. C., aged 43, housewife.

Twenty years ago a bullous eruption began on the right side of the neck and recurred in attacks lasting six to eight weeks during the summer months only. Seventeen years ago the attacks became more severe, involving both sides of the neck, and a year later blistering and fissuring occurred in the axillæ. The lesions only appeared in hot summers; during cool summers she was completely free. Five years ago blisters and maceration occurred in the groins. Two years ago she was given a course of intramuscular penicillin injections with no effect, since when the eruption has been almost continuous, except during June of this year (1949).

Family history.—One brother has similar lesions in the inguinal region. Her father and paternal grandmother had a similar eruption.

On examination.—The scalp is clear. There are pigmented macules on the side of the neck. The axillæ have central maceration with fissuring, peripheral pigmentation and small bullæ. The inner aspects of the thighs show grouped lichenified papules. The skin of the groins is spongy and fissured. Nikolski's sign is negative. The nails are normal.

Investigations.—Blood-count within normal limits.

Tzanck test: The smear showed dyskeratotic cells.

Histology (Dr. H. Haber).—"The epidermis shows mild hyperkeratosis, patchy parakeratosis and irregular acanthosis. Within the stratum malpighii there are clefts running partly parallel and partly perpendicular to the surface of the epidermis. The clefts have developed into true intra-epidermal bullæ. This change in the epidermis is due to a dyskeratosis of the malpighian cells. They have lost their prickles and have become spherical. Individual and groups of dyskeratotic cells are clearly visible within the bullæ. There is another group of cells scattered within the epidermis which show a granular degeneration of their cytoplasm. The masses appear as purple globules within the cell itself and seem to press the nucleus to the periphery. The nuclei in these cells appear flattened or half-moon-shaped. Cytological scrapings show these cells in a considerable number.

Corps ronds or grains are absent. The upper corium shows a diffuse round-cell infiltration. The elastica appears atrophic in the stratum papillare and subpapillare and looks normal in the rest of the cutis. The appendages show no change.

"Familial benign chronic pemphigus (Hailey-Hailey)."

Comment (Dr. Cairns).—The problem with any new clinical entity such as this is whether it is a relatively fixed variant of some known disease or a disease *sui generis*. Cases have been recorded conforming closely, both clinically and histologically, with those presented to-day. Pels and Goodman (1939), described such a case as "Darier's disease with vesiculation". Hailey and Hailey (1939) introduced the term "familial benign chronic pemphigus", and Ayres and Anderson (1939) reported on five cases under the title "recurrent herpetiform dermatitis repens". The condition was familial in four of their cases. Becker and Obermayer (1940) suggested the term "dyskeratosis bullosa hereditaria".

Although histologically such cases are reminiscent of Darier's disease, I think it more likely that the disorder should be related to epidermolysis bullosa on account of the frequent familial incidence and association with trauma.

General Discussion on the Four Cases of Benign Pemphigus

Dr. F. F. Hellier: We are fortunate to-day in seeing so many cases of this condition. It cannot be a new disease and I am wondering what diagnosis was given in the past to such cases. I have seen one or two very similar patients who have usually been labelled, rather unhappily, pemphigus vegetans; looking back I feel sure that they have had this condition. The histology is strikingly like what is found in Darier's disease although there is not much clinical resemblance. One point which may have some bearing is that, in patients with Darier's disease, French workers have shown that pathological lesions occur on normal skin following exposure to actinic rays. In the cases under discussion a rather similar feature is that they are mostly worse in hot weather.

Dr. W. J. O'Donovan: We are much indebted to Dr. Cairns for presenting his cases as linked on to an established and recognized group of phenomena and not as examples of a self-existing entity. I have seen this condition previously and because of its association with friction, its unmistakable inheritance and its non-progressive state I have labelled it as a fragilitas dermis. To describe this condition, and others, as a distinct thing discovered at a point in historical time and linked with the name of its first observer is, I think, most respectfully, a rather strong assumption that the disease was missed by the very great clinicians of the past. The addition of names to names in dermatology is burdensome to the newcomer and brings upon us the reproach of physicians who are abandoning this habit in the wide and unitary consideration of cases that now obtains in general medicine.

Dr. Sydney Thomson: I am rather worried about Dr. O'Donovan's objection to the name which has been given to the condition. Even if he calls it "fragilitas dermis", it is still a name attached to it and one which is less distinctive. Certainly when this disease is seen it presents a very definite picture. The changes seen in the axillæ of Dr. Coles' case are most striking, the curious velvety appearance being quite unique and not really coarse enough to be a pyogenic papillomatosis.

The President: Seeing all these cases together, I am inclined to consider this disorder a clinical entity.

Dr. O'Donovan: I do not wish to question Dr. Sydney Thomson's method of approach to dermatology. Our art can be practised by recognitional means by having the exact clinical pictures and by comparing case with case. When Baretta's moulages began to be collected in Paris, French clinical dermatology reached a very high pitch of precision, but I would suggest to our young colleagues that they can practise dermatology to-day by considering more the processes taking place and using a nomenclature that groups together similarities of process; and it was because Dr. Cairns adopted this that I ventured to congratulate him, and I still do, on stressing similarities rather than making a particular point of a new, or almost new, identifiable separate disease.

Dr. F. R. Bettley: I wonder what eventually happens to these cases. I had a patient of this sort in 1938, but afterwards lost sight of him. Quite recently I found that he had got much worse and died in 1941, diagnosed as a case of pemphigus vegetans.

Dr. Gold: The mother of my patient, who suffered from the same condition, died in old age. My patient is 69, and has had the condition for twenty-nine years. It has not become worse during recent years.

Dr. Coles: The mother of our patient shown to-day has had the condition. She is now 64, and is vastly improved. She has had no trouble in recent years except a little during the early summer of this year. One of her sisters, now dead, was affected, but did not die from the condition as far as we know.

Light-Sensitization.—H. W. BARBER, F.R.C.P., and PETER SMITH, M.R.C.P.

Mrs. V. B., aged 43.

At the age of 7 the patient developed eczema of the face and neck following several months' hospital and sanatorium treatment for pulmonary tuberculosis. In the next ten years the rash began to involve the trunk and limbs, especially the light-exposed areas. Since then acute attacks have followed exposure to sunlight and have necessitated her staying indoors much of the time in the summer. There is considerable improvement in the winter months. The irritation is often increased a few days before and during the periods.

General health has been good apart from an attack of pleurisy and bronchitis at the age of 25, for which she was kept in bed six weeks.

Family history.—The father suffered from asthma, and the mother died of tuberculosis at the age of 39. One sister has diabetes, and the brother died of tuberculous meningitis.

Present condition.—In May 1949 the face, ears, anterior part of neck, hands, forearms and shins showed a chronic lichenified erythematous and papular eczema. General physical examination revealed no abnormality with the exception of a liver enlarged to three finger-breadths below the costal margin. Investigations failed to explain this enlargement.

Investigations.—Blood count within normal limits.

Blood urea: 27 mg./100 ml. Liver function tests normal. Urine normal; no porphyrins found. Chest X-ray normal. Mantoux test: Old Tuberculin, 0·1 ml. of 1 : 1,000 gave a strongly positive response with local erythema, induration and spread along the lymphatics, followed by an eczematous reaction on the red area.

Progress and treatment.—In previous years all local applications of light-protective substance have proved valueless, and radiotherapy and œstrogens have been equally disappointing. Investigations in hospital failed to detect any underlying abnormality, except a markedly positive Mantoux reaction in a patient whose light sensitivity followed an attack of pulmonary tuberculosis. In case there may have been some relationship between the development of these two hypersensitivities it was decided to start a desensitizing course of tuberculin. On June 27 the first dose of Old Tuberculin 0·00001 mg. was given intradermally, and the dose was increased each week until 0·0624 mg. was reached on September 25. These doses were tolerated with slight local reaction for the first two months, but more recently there has been a typical tuberculin response appearing twelve hours after the injection as an indurated erythema 3–4 cm. in diameter, and on one occasion, a focal eczematous reaction at all the sites of previous injections.

A tuberculin jelly patch test performed on October 12 was negative.

No other general or local treatment has been given since May, and never has the light sensitivity been less than it was this summer.

Dr. H. W. Barber: When I first saw this patient, I realized that her light-sensitiveness was of what I term the "adult" type, i.e. epidermal sensitiveness with eczematization, severe itching, and secondary lichenification. But in these cases the sensitivity nearly always begins in middle-life, whereas in her case it began in childhood.

Dr. R. Kauntze kindly admitted her for investigation. The adult cases usually show evidence of hepatic insufficiency, but investigations for this were negative, and the only striking features were the family and personal history of tuberculosis and the reaction to the Mantoux intradermal test to tuberculin, the site of which became acutely eczematized. This suggested that her initial infection with tuberculosis in childhood had sensitized the skin to light.

I would not stress too much the therapeutic effect of the intradermal injections of tuberculin as their action may have been non-specific.

Dr. O'Donovan: The tuberculous causation of this condition has been a matter of consideration, of search and research for some decades. I confess I had given up stimulating my assistants to persevere in this for a long time, but when my friend and colleague, Dr. Barber, shows that he pursues this line of investigation with some hope we shall all be stimulated once more to include this, at least for a while, once more in our routine investigation of this type of case.

Ichthyosis Congenita—Early and Late Phases.—C. H. WHITTLE, M.D., and A. LYELL, M.B.

The two patients shown represent two families affected with ichthyosis congenita.

CASE I.—Infant aged 3 months.

In the first family there have been two affected infants both of whom we have examined. Their lesions were identical in kind; in degree the elder was more severe, and survived only

two days. They both showed the characteristic features of the condition—ectropion, eclabium, deformity of the nose and ears, flexion of the digits, and the body covered in a glistening skin, which in both cases had already fissured at the time of birth, though less so in the surviving infant. The name of "collodion fœtus" is derived from this covering. The infant who died was healthy apart from the skin, and, in particular, the post-mortem failed to reveal any endocrine abnormality. The chief histological change in the skin in both cases was hyperkeratosis. The surviving infant's skin proceeded to exfoliate, and after a week the ectropion and other facial deformities had disappeared; in a month the last traces of the "collodion" had gone from the hands and feet. At the age of 3 months the skin remains slightly scaly, but the child is thriving.

CASE II.—The girl, aged 18, represents the second family, in which there were also two affected children. They were "collodion fœtuses" according to their mother's account, which is very circumstantial. This girl now has an ichthyosis of the abdomen and back, involving the groins, and to a lesser extent the axillæ, but sparing the limbs, whose skin is normal.

The details of the family histories are shown below. The affected members are indicated by ♀ ♂

In neither family was there any consanguinity or skin disease.

In conclusion there are two interesting speculations. First, what will happen to the baby? We think that it may recover completely, and are supported in this by the literature. Second, what is the diagnosis of the 18-year-old girl? Has she got ichthyosis vulgaris? Or does the normal skin of her limbs and the mild involvement of the axillæ justify a diagnosis of Brocq's ichthyosiform erythrodermia?

The President: It is extraordinary how rapidly such babies recover, though often incompletely, from their original alarming state.

Chronic Granuloma of the Nose: For Diagnosis.—R. H. MEARA, M.R.C.P. (for W. N. GOLDSMITH, M.D.)

S. P., a Singhalese male, aged 55, who has been resident in this country since 1917.

The patient noticed a small papule on the nose ten years ago. Similar papules appeared nearby forming a lobulated soft mass which enlarged by peripheral extension until it involved most of the surface of the nose and, a few years ago, spread on to the left cheek. About five years ago a pustular eruption appeared on the chin and this has persisted. His general health has been unimpaired.

On examination.—There is a purplish lobulated fleshy mass growing over the nose and extending on to the left cheek (Fig. 1). Sebaceous material can be expressed from this lesion, which is not tender. The mucosal surfaces are not involved. There are also some pustular follicular lesions of the chin.

Investigations.—Wassermann reaction negative.

Smear of tissue from lesion: No acid-fast bacilli or Leishman-Donovan bodies seen in suitably stained specimens.

Culture of tissue from lesion: Bacteriological: *Staphylococcus pyogenes aureus* cultivated. Mycological: No growth after four weeks' culture on beer-wort agar.

Histological examination.—A biopsy was performed on a tumour in the left naso-labial furrow. In the middle of the section is a dense infiltrate, closely bunched up around the upper three-fourths of a hair follicle which is degenerate. Elsewhere there is a less heavy infiltrate, mainly perivascular. The infiltrate is composed predominantly of plasma cells together with proliferative connective tissue elements and capillaries (Fig. 2). The histology points to the lesion being a granuloma.

Histological examination of a lesion of the nose in 1941 showed a similar picture.

The President: The lesions are very sharply defined for rosacea and the regular culture of *Staph. pyogenes aureus* is against rosacea.

FIG. 1.—Facial appearance, September 1949.

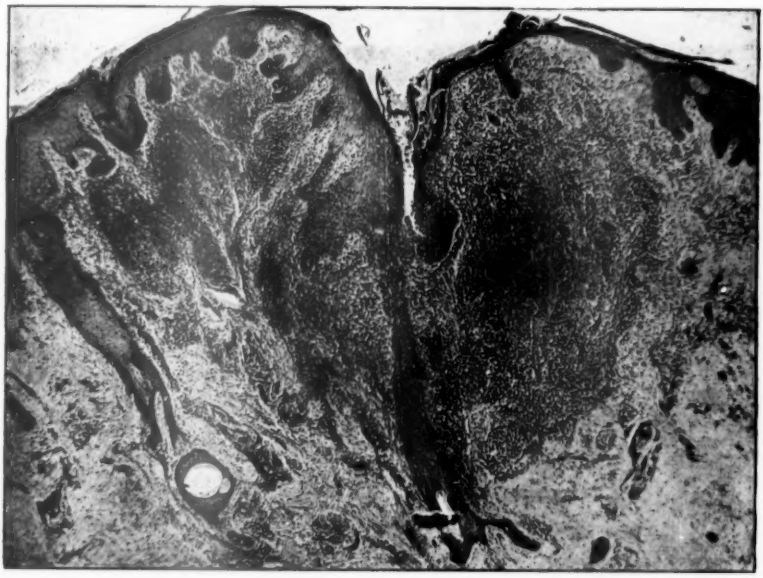

FIG. 2.—Photomicrograph of skin section. (× 50.)

ADDENDUM (23.1.50): Since the above report was written the lesions of the chin have coalesced to form a raised plaque similar in nature to the tumours of the nose. The blood Kahn reaction has become positive but the condition has not responded to anti-luetic treatment. Subsequent cultures of tissue from the nasal lesion have yielded an anaerobic streptococcus and no *Staph. pyogenes aureus* has been isolated in these later cultures. However, a staphylococcal or other cause for this condition is still uncertain. R. H. M.

Localized Pili Torti.—O. L. S. SCOTT, M.B., M.R.C.P.

This patient, a girl of 11, was bitten by an insect on the scalp two years ago. The bite became septic and was incised. Following this, the hair fell out over the lesion, leaving a circular patch about 2–3 inches in diameter. This was bald for three to four months, after which re-growth commenced. The fresh growth of hair was twisted, unlike the rest of the scalp hair. The distortion has diminished lately, and is not so well marked as when first seen some months ago. Microscopically, the hair is twisted in several places through 180 degrees and shows signs of early fracture. [Slide shown.]

Comment.—All cases of pili torti in the literature have the whole scalp involved, sometimes even the eyebrows. The condition seems to be a faulty growth of new hairs, with baldness as an essential preliminary. It usually appears in children aged 1–2 years who have previously been bald, but it has been reported in adults after shedding of the hair. The individual hair is usually short, easily broken and twisted through 180 degrees in several places. It has a strange glint, due to unequal reflexion of light from the twisted hairs.

I have not been able to trace another report of *localized* pili torti. This case fulfils the criteria of pili torti as laid down by Hellier in *Brit. J. Derm.* (1940), **52**, 173.

Dr. H. J. Wallace: It has been suggested that in this case the area might be epilated with X-rays. Such treatment is, however, unlikely to be effective and is not devoid of risk.

The following cases were also shown:

Recurrent Painful Nodules of the Limbs.—Dr. R. M. B. MACKENNA and Dr. E. LIPMAN COHEN.

Congenital Hæmangiectatic Hypertrophy of Ear.—Dr. R. E. CHURCH (for Dr. C. H. WHITTLE).

Phenolphthalein Eruption of Unusual Type.—Dr. DAPHNE ANDERSON.

Pseudoxanthoma Elasticum with Angioid Streaks in the Retinæ (Groenblad-Strandberg Syndrome).—Dr. F. J. JENNER.

Schamberg's Disease.—Dr. E. LIPMAN COHEN.

(These cases may be published later in the *British Journal of Dermatology*.)

Section of Ophthalmology

President—M. L. HINE, M.D., F.R.C.S.

[*October* 13, 1949]

Change and Progress in Ophthalmology

PRESIDENT'S ADDRESS

By M. L. HINE, M.D., F.R.C.S.

IN 1926 our then President, the late Mr. Ernest Clarke, gave a wide review on the progress of Ophthalmology from 1881 to 1926 (*Proc. R. Soc. Med.*, **20**, 70), and this would appear a suitable occasion to continue where he left off, as much has happened in the last twenty-three years. In many cases treatment has improved, new or more perfected operations are being performed, and recently discovered remedies are being used with remarkable results. In addition a lot of spadework has been done on the pathology and biochemistry of the eye, which while, perhaps, not yet yielding its full harvest, may still do so in the future.

OPERATIVE TREATMENT

Detachment of the Retina

The most spectacular advance in surgical treatment has, of course, been that for detachment of the retina, and this dates only from 1929, when Gonin gave, to a rather incredulous Congress at Amsterdam, the results of his patient work over the previous four or five years. After Sir William Lister and Charles Goulden had paid a visit to Lausanne, to study Gonin's methods and results on the spot, the first Gonin type of operation was done at Moorfields in 1930 and I well remember doing my own first one, with very satisfactory result, in February 1931.

During the next year or two ways of obtaining a less localized reaction in the choroid and retina were sought for in this country and abroad and, ultimately, after some considerable trial and error, very weak diathermic currents were found the most suitable and shortly replaced the cautery. This was in 1933, only sixteen years ago. Some favoured the perforating points, others the surface method, while others combined the two. Since that time it can quite fairly be said that, of all unselected cases, some 50% have been successfully treated, according to my observations published in 1944 (*Brit. J. Ophthal.*, **28**, 515) though a considerably higher percentage

cure can be obtained when the material to work on is of better quality and the operator more and more experienced. Arruga, I think very fairly, put it last year at 75%. At any rate this is a very different story from that of the pre-Gonin days, when less than 1% of all detachments were cured by puncture of the sclera down and out, or recovered spontaneously after prolonged rest in bed. When one looks back it seems almost a miracle how, in the course of a year or two after 1929, the teaching on detachments varied from "Holes are hopeless" to "Holes are hopeful".

The success of the operation and the general opinion that most cases of this nature should undergo it have certainly created a problem for the ophthalmic hospitals throughout the country in these days of long waiting lists and nursing shortage. Most cases are of the urgent variety and cannot be kept waiting very long, if at all, before admission. After operation they need a prolonged period of careful nursing for, at any rate, three weeks, occupying much sought after beds. Whereas in 1926 there were 12 scleral punctures done at Moorfields for detached retina, and 8 at the Royal Westminster, in 1947 there were 376 patients operated on by the modern method at the former hospital and 129 at the latter. This problem has still to be solved.

Intracapsular Extraction

A less spectacular advance in operative treatment, less spectacular because it has been more gradual, is the general adoption, in suitable cases, of the intracapsular operation for extraction of cataract. The operation is not a new one and, in 1932, Sinclair, in his Presidential Address to the Annual Congress of the O.S.U.K. at Edinburgh, gave a very full account of its origin. He himself had started operating by this method in 1918, but only as the technique of forceps extraction gradually improved under his guidance and that of Elschnig of Prague and Arnold Knapp in America did it become relatively safe; at the time of his Address practically none were being done in Britain outside Edinburgh. In 1921–2 Foster Moore and Affleck Greeves had used Barraquer's suction method for some months, but the operation was discarded at Moorfields. Apart from this, the first record of an intracapsular extraction to be found in the Moorfields reports is for the year 1932, evidently a response to Sinclair's Address. In 1939 1·7% of all cataract extractions were of this nature at the Royal Westminster. But at the present time all over Britain, as well as in America and on the Continent, this operation is being done in steadily increasing numbers. In 1947 14·25% of all extractions were intracapsular at Moorfields and 12·2% at the Royal Westminster. This percentage seems likely to rise still further as each older and more conservatively minded surgeon is replaced by a younger one. When used with judgment and performed with the necessary skill it must be considered a distinct step forward, not to be overlooked in any progress report.

Squint Operations and Orthoptics

We next come to a very interesting study, which, I believe, must show to everyone the marked influence "Orthoptics", as popularly designated, has had on the treatment of squint. This is a comparison of figures for operations on such cases in 1926 with those for 1947. Orthoptics is by no means a new science, but, prior to 1930, it was not so extensively studied as it now is, nor with such adequate instruments.

It was in that year that the first orthoptic department in a British ophthalmic hospital was opened at the Royal Westminster Ophthalmic and, after that, a new race of "Medical Auxiliaries" rapidly developed. Whatever contrary opinions there may be as to the *extent* of their value in the treatment of squint, there is no doubt whatsoever that orthoptics has come to stay, and that these departments are of great assistance to ophthalmic surgeons; they have influenced their opinion on

operative procedures, including those on the oblique muscles and the superior and inferior recti, and stimulated them to employ the more graded and controllable operations now in use.

Recession of the internal rectus was suggested and practised by Jameson in America in 1922, but did not come into general favour till much later. Williamson-Noble read a paper on "Graded Squint Operations" before the O.S.U.K. in 1929, but the first record I can find in the R.W.O.H. reports is for the year 1931, just after the opening of the Orthoptic Department. In that year seven were done, followed the next year by eleven; since that time the numbers have steadily grown until, as can be seen in Table I, there were 148 such operations in 1947.

Myectomy of the inferior oblique has been done from time to time for over a hundred years, but it is only during the past twenty years that it has been used scientifically. At the present time further improvements in technique are still taking place, and there is a tendency for recession of this muscle to take the place of myectomy in the less marked cases of overaction or contracture.

The first mention of this operation at the Royal Westminster is for the year 1935, when 5 were done, followed in 1936 by 18, with 25 in 1947.

For simplicity in the table I have classed the "resection" operations with the advancements; though technically they may not be identical, in practice they come to the same thing. When considering the figures and comparing what may be called the pre-orthoptic era with the post-orthoptic it must be remembered that squint operations have a very low priority for admittance in these days and that the figures given here for such operations would be much higher if there were no waiting list, on which, at the present time, there are 800 cases for the Moorfields Group.

TABLE I.—OPERATIONS FOR SQUINT

1926	*R.L.O.*	*R.W.O.*
Advancement	20	20
Tenotomy	28	14
Advancement and tenotomy	109	66
Tenotomy with reef stitch	11	—
Various	—	6
Total	168	106
1947		
Advancement (or resection)	31	5
Tenotomy	19	22
Advancement and tenotomy	104	18
Tenotomy (3 snip)	—	7
Advancement and 3 snip		5
Recession	101	148
Advancement and recession	176	161
Myectomy	18	25
Various	30	34
Total	479	425

		R.W.O.H.
First recession	1931	7
First myectomy	1935	5

From the figures given I have myself no doubt that the greater choice of operative technique is a very definite advance on the older and less selective methods, and that the numbers dealt with show the greater care that is being taken in the management of these cases.

Dacryocystorhinostomy

I was rather surprised a few weeks ago when our R.M.O. at the Royal Westminster told me that he had never seen an excision of a lacrimal sac, and only a few days ago his successor told me that the same applied to him. Here was a rather surprising

change in operative treatment, which, on enquiry, I have found to be a definite improvement, though a rather time-consuming one.

In 1926, 96 sacs were excised at Moorfields and 23 at the Royal Westminster. In 1947 the numbers were 44 and 9. But in the latter year 46 dacryocystorhinostomies were done at Moorfields and 22 at the Royal Westminster, while in 1948 the figures for the latter were 3 excisions of sac, and 47 dacryocystorhinostomies.

Once again the operation is not a new one, as Toti first advocated the external route fifty years ago and West the intranasal route in 1920. The operation became the field of the nasal surgeon and not many were done. Some 4 cases a year were sent from the R.W.O.H. to the nose surgeon at Charing Cross between 1926 and 1939. The first record of this operation in the Moorfields reports is in 1932, when the nasal surgeon assisted.

Leighton Davies, in 1934, in a discussion in this Section, certainly stated that he had been using this method for the past twenty years, Pooley in 1925 read a paper describing a rather rough-and-ready operation of this type which he employed in Sheffield, and Traquair in 1932 recorded a number of cases done during the previous few years. But it was not till 1944 that it became increasingly an operation of election amongst ophthalmic surgeons in this country and America, and since that time it has been found to give results which are so marked an improvement on those obtained by the older operation that a majority of surgeons now claim that excision of the sac should never be done except for really old people.

Corneal Grafting

In 1926 corneal grafting had no place in our operative procedures, and all development of this operation in this country dates from the preliminary experimental work of Tudor Thomas from 1930 to 1934, stimulated by the gradual development of a satisfactory technique by Elschnig of Prague between 1923 and 1930.

The first successful graft on a human eye in Britain was done in 1933, and nowadays it is an operation undertaken by many ophthalmic surgeons when a suitable occasion arises. I see that in 1947 5 cases were done at Moorfields and 4 at the Royal Westminster. Long-term results have given rise to some disappointment, but the cases which have permanently benefited are a justification for all the work which has been done, and hold out increasing hope for the future.

Magnet Extraction

I cannot leave this review of changing operative methods without mentioning the changed outlook during the past few years on the extraction of magnetic foreign bodies from the vitreous. It is true that in the 1908 edition of Fuchs' Text Book of Ophthalmology, Duane made the statement that "many prefer even with the Giant Magnet, to make an incision in the sclera as close as possible to the site of the foreign body, previously located by X-rays", but the posterior route never had as many adherents as the anterior. Today the position is largely reversed, partly because so much of the alloy steel now used in the manufacture of tools as well as of weapons of destruction, is only feebly magnetic, and partly because, in these days of diathermic coagulation, surgeons are less chary of making direct approach to the vitreous. It is another sign that ophthalmic surgeons can adapt their methods to the needs of the times.

Non-operative Treatment

Contact Lenses

Passing on to changes in non-operative treatment contact lenses may first be mentioned. The history of their development is concisely given in the recent Vol. IV of Duke-Elder's Text Book of Ophthalmology, and I need only state here that in 1926

it was only very rarely that such a lens was ordered, of the Zeiss type and for conical cornea. The occurrence of large numbers of cases of delayed gas keratitis after the first World War led to the improvement of the Müller type of lens, which was found a more effective form of corneal protection than the Zeiss type, but it was not till 1937 that large-scale facilities for the provision of these lenses became available in this country, first in London, and later in all large centres. As usual, once a facility is provided, fresh uses are found for it and this has certainly proved true of contact lenses. Every new treatment has both its enthusiasts and its detractors, and, in this case, as Cross has recently shown, it is the mean between the two opinions which is proving correct. I learn that some 2,000 patients per annum are supplied with them in Britain, while in America they are being produced in very large numbers.

Transparent Plastic

The adoption of transparent plastic as a suitable substance with which to make some optical appliances is another development of the past twenty years. It was first made by the Imperial Chemical Industries in 1925, but it was not till 1938 that it was first used for making light-weight and unbreakable spectacle lenses. These did not become generally available till 1943, though in 1942 many thousands were sent to Russia. These lenses are as yet too liable to get scratched, but this difficulty is likely soon to be overcome. Quite recently it has been made possible to obtain bifocal lenses, with certain limitations, of this type.

This material has also been more recently adopted for the manufacture of contact lenses and artificial eyes.

Operative Aids

Certain operative aids, now almost routine, were not used in 1926, save very occasionally and individually.

Retrobulbar injections of novocain began to be popularized in 1930, though they had been regularly used by Elschnig a few years before that date, for his intracapsular extractions.

Akinesia of the orbicularis was being practised by Sinclair in 1930, having originally been suggested by Van Lint as long ago as 1914, but it did not come into routine use till approximately 1935–36.

As previously mentioned, diathermy was only adapted for use in ophthalmic operations in 1933, originally for detached retina. Since that time many other uses have been found for it, as Weve showed in his Bowman Lecture in 1939, and the modern surgeon would be very handicapped without it.

We must not forget also that radon seeds for the treatment of intra-ocular neoplasms were first used by Foster Moore in 1929, and, soon after, fractional doses of X-rays were introduced for the same purpose by Martin and Rees in America.

Therapeutic Measures

As regards the newer drugs, Sulphonamides, Penicillin, E.3 and D.F.P., their introduction is so recent that I need only mention them briefly to complete this review.

The German sulphonamide compound, Prontosil, made its appearance in 1935, but only on very rare and individual occasions was it used in this country for streptococcal infections of the eye. It was not till sulphapyridine was manufactured and tested in 1938 that large-scale clinical trials in cases of streptococcal and gonococcal infections of the eye gradually took place. The less toxic sulphathiazole, sulphadiazine and sulphamezathine came one by one a little later, the last in 1942.

In that year, at a discussion at the Annual Congress of the O.S.U.K. on the uses of these sulpha drugs in ophthalmic practice, it was shown that the treatment of ophthalmia neonatorum had already been revolutionized, and that they were of great benefit in streptococcal and pneumococcal infections of the conjunctiva and lacrimal sac. Their value was still being assessed and discussed when penicillin arrived on the scene. The latter was first tried in ophthalmological practice, on a small scale, at the instigation of Professor Florey, at the Oxford Eye Hospital in 1941, but until 1945 supplies were very small and almost all went to the Services. Though not the cure-all popular belief would have it to be, partly because of the difficulties of getting effective concentration in the eyeball, and partly because all organisms are not penicillin sensitive, there is of course no doubt about the great value of penicillin in ophthalmological practice, or that both it and the sulpha drugs have given us an entirely altered outlook on the result of numerous infections of the eye. Ophthalmia neonatorum is only one example. As a more penicillin- or sulphonamide-resistant race of organisms develops we are likely to hear more in the future of other antibiotics, perhaps aureomycin, and one day we may be able to deal successfully with the various virus infections including herpes simplex.

Like penicillin and, to a very large extent, the sulpha drugs, the other two recent additions to our therapeutic equipment, E.3, and D.F.P. are due to British initiative. E.3, the non-irritating synthetic mydriatic, is a product of wartime research, stimulated by the shortage of atropine in 1942–43. Clinical trial was undertaken at Oxford in 1943, and soon after at Moorfields, but it did not become generally available till 1944. It is a definite addition to our therapy, especially in those cases which are, or become, allergic to all mydriatics.

D.F.P., the newest powerful miotic, able to quickly overcome the effects of atropine, is, still more, a wartime development in that it is a diluted product of one of the gases tried out for gas warfare, and, fortunately, never used for that purpose. The effect of this gas in contracting the pupil was noticed first in experimental animals, and this started further experimentation with very dilute solutions, leading to clinical trials which gave promising results, and, in 1946, a further addition to our therapeutic resources.

Brucellosis and Toxoplasmosis

Before I end, I must make brief mention of the research on brucellosis and toxoplasmosis, which has been going on during the past few years on the Continent and in America, work in which ophthalmologists have taken their full share, and I must not omit the clarification of the vascular changes in diabetes by Ballantyne and Lowenstein, work which has stimulated our medical colleagues and pathologists to further investigations.

Though much of what I have brought forward has been illustrated from local sources, I should like to say here that I am certainly not claiming these various advances for British Ophthalmology alone, but for Ophthalmology as a whole; it is international, and in some cases we follow where others lead, while in others it is certainly vice versa.

I know that I have by no means exhausted the subject, and feel that many useful additions could be made; but I think that I have said enough to show that real and steady progress is taking place in Ophthalmology through the adoption of new methods and a gradual improvement of older ones. I hope that this review will stimulate us to further efforts, so that progress may continue. I also hope that more and more mass records as to the results of various treatments and more long-term reviews will steadily become available. These will then be the basis on which some successor of mine in this office will be able, in due season, to give a still more comparative and accurate record of progress during the next period.

President—GAVIN YOUNG, M.C., M.B., F.R.F.P.S.Glas.

[*November* 4, 1949]

Aural Cholesteatoma—or Cholesteatosis. A Review

PRESIDENT'S ADDRESS

By GAVIN YOUNG, M.C., M.B., F.R.F.P.S.Glas.

IN the writings on this subject, cholesteatoma is referred to, usually, as being either primary or secondary. Pathologists and neurosurgeons have described the former type as the "pearl tumour", or nowadays as an epidermoid. It is met in the bones of the skull, most commonly in the temporal bone, and also, though very rarely, in the substance of the brain.

Jefferson (1938) has published a series of 6 cases of slowly developing unilateral facial paralysis accompanied by some deafness and shown at operation to be due to epidermoid growths. The first case was that of a typical epidermoid, though there was a history of otorrhœa at times in the past. At operation, a large epidermoid was removed which filled almost the whole petrous. The feature of interest and importance in the case was that the mastoid process was normally cellular. In 3 of the cases there was no history of otorrhœa. The other 3 had exhibited suppurative otitis media at one time, but the ears were dry and uninfected at the time of operation. Primary cholesteatoma has been described from time to time by otologists also, but I personally have never encountered a real primary cholesteatoma, or epidermoid, in the mastoid process in the course of some thousands of mastoid operations. I believe with many others that the time has come for a change of nomenclature.

The Greek suffix—*ωμα*, suggests "swelling", and its use has been associated traditionally, in medical terminology, with tumour. There are exceptions, glaucoma and trachoma, for instance, in which the original sense of the suffix has been preserved. The hypothesis of tumour-formation had, of course, something to support it. "Tumour" was the description most apposite to the early otologist when he encountered this foreign, soft mass which had made for itself a bed in densely hard bone. Not merely did the mass resemble a tumour growing at the expense of the surrounding tissues, no matter how dense, but also it had the appearance of local malignancy because of recurrence, in some cases, even after thorough exenteration.

The modern view, however, is that cholesteatoma is not a tumour, and I suggest that the suffix—*ωσις*, meaning "containing" or "full of", may give us a term more suitably descriptive, and more in accordance with recent theories of the pathogenesis of the condition. I propose, then, to speak of "Cholesteatosis".

In my experience, cases of very extensive cholesteatosis are not so common now as they were thirty years ago. The most extensive case I have ever seen occurred in 1914. This was a massive affair which had eroded into the middle fossa and had lifted the brain from the floor of the middle fossa over a wide area. There had been an extradural abscess, lateral sinus thrombosis and a cerebellar abscess—from all of which the patient recovered, after a stormy time, under Kerr Love's patient care. I think that the lessening incidence of this type of case may be due to earlier recognition of the condition, and a disposition, generally, towards earlier operation. There are also many more adequately trained otologists to attend to the work.

Signs and Symptoms

There is usually a history of otorrhœa, either persistent or intermittent, and this is always characteristically malodorous. Since the attic is always the site of the disease from the beginning, the hearing acuity is usually defective, sometimes markedly so. Headache is a fairly common complaint, especially where the discharge is intermittent. If syringing be employed to remove débris the surface of the returned lotion commonly presents an oily appearance, caused by the presence of a fine layer of squames, floating on the surface. Its appearance resembles that of the lotion returned in an antral proof-puncture where a mucocele or retention cyst has been punctured, and disorganized débris and squames are washed out of the antral cavity. Chronicity of disease may be accompanied by extensive damage to the drumhead, to the membrana tensa as well as to Shrapnell's membrane, with protrusion of cholesteatosis from the region of the attic. Members who have attempted to remove the débris of cholesteatosis through the meatus will recollect how tightly the débris is packed and how difficult it may be to remove. I shall allude to this circumstance later. Other signs and symptoms, such as vertigo, elevation of temperature, evidence of increased intracranial pressure, or of a generalized systemic infection, will depend upon the extent and the direction of erosion.

In these cases, the massive type in which the resemblance to a cyst or tumour gave rise to the name cholesteatoma, the pathological entity is a smooth-walled silvery cyst, lying in a bony cavity and easily detached from its bed. The cyst wall consists of concentric layers of epithelium, the parietal surface actively growing and shedding squames, so that the wall is a series of successive layers. Growth of the cyst is probably fairly constant, and takes place *pari passu* with the increase in the contents of the cyst. These are squames, mycelia, cholesterin crystals whose presence is due to the breaking down of the epithelial elements, and the products generally of suppuration.

There has been speculation on the exact procedure of the growth of the cyst. In my view growth progresses at the expense of the surrounding bone by simple pressure erosion, a common thing in pathology. The aortic aneurysm may erode the anterior aspect of the vertebral bodies. One sees repeatedly, invading the antrum, the maxillary cyst, either periodontal or dentigerous, which has grown at the expense of the floor and the anterior wall of the antrum to such an extent as to produce the state of egg-shell crackling. There is an aphorism in pathology that intermittent pressure may cause hypertrophic reaction of the opposing tissues, constant pressure causing atrophy.

I have indicated that the contents of the sac may be firmly held. The principal single factor in promoting growth may well be the introduction of moisture. As Day (1934) has said, cholesteatoma is markedly hygroscopic, and moisture will cause the mass to swell and to exert pressure on the surrounding tissues, even on dense bone. It is likely that the process is one of local anæmia, with atrophy, of the surrounding bone. The presence of moisture, warmth and dead tissue affords a favourable medium for bacterial growth. Day believed that the most important factor in the development and growth of cholesteatoma is the presence of moisture. Whether the moisture is due to suppuration, is a transudate or an exudate or even water, the effect is the same. The surface epithelium of the body does not tolerate well the continued presence of moisture, which causes irritation and degeneration of epithelium.

Under this motive force of growth, cholesteatosis may be regarded as locally malignant, as running wild, and indeed any of the important structures related to the tympanic and mastoid regions may be eroded and destroyed. The condition is not commonly sterile, unless the attic perforation has closed, or, probably very rarely, has never existed. The infection is likely to be of a low-grade type, setting up a degree of local protection, a sort of local immunity. This may be broken down by the introduction of a fresh infection, or by some factor which has caused lowering of local or general resistance, either "chill" or trauma, when a flare-up, with more copious pus formation, under pressure, will transform the condition clinically into an affair of emergency.

In the literature there are many references to the ravages caused by cholesteatosis, and it is this fact, and the necessity of the earliest possible recognition of the condition, which have impelled me to choose this subject for my Address. A spectacular type of case is that in which the radical mastoid operation has been performed by the process of disease. There are those cases, also, in which the widening of the aditus by the cholesteatosis has not quite attained the complete erosion of the bridge. These two types of case are not at all uncommon. Of the considerable number that I have seen, the best result in my recollection was the case of the wife, aged 40, of a colleague, who presented a perfectly healed radical mastoid cavity, never having undergone operation, but having suffered from otorrhœa in childhood. Another point of interest in this connexion was that a son of this patient underwent the mastoid operation at the age of 4, for cholesteatoma, the ear having discharged from infancy. In the case of the mother, the aditus and meatal drainage were widely patent, which doubtless accounted for the fact that the ear was dry, and that cholesteatosis had ceased to form. Others that have been seen in the past have continued to desquamate, with fœtor, and to form the silvery lining membrane. In such cases, the facial ridge has not been lowered sufficiently by the disease to provide easy, unimpeded drainage, with subsequent natural healing.

In contradistinction to Jefferson's cases of epidermoids, Lundgren (1948) reports 4 cases of apex (petrous) cholesteatosis causing progressive facial paralysis, secondarily to mastoid cholesteatosis. In each of these cases there was ample evidence, in middle ear and mastoid, of the presence of cholesteatosis. Indeed the radical operation had been performed in 2 of the cases. Also in the recent literature, Nilsson (1948) reports a case of attic cholesteatosis, following a longitudinal fracture of the petrous. The case is not without interest, being that of a man who suffered a severe skull injury, with bleeding from the ear, and slight facial paralysis, left side. The immediate evidence of damage cleared up save for a slight hearing defect. There was neither discharge from, nor pain in, the affected ear until eleven years later when he developed an epitympanitis with foul-smelling discharge for which he underwent the radical operation. There was cholesteatosis in the attic, but the mastoid process was normally cellular and showed no disease. The normal pneumatization, as I shall remind you later, was unusual.

Pathogenesis

In the past twenty years there have been published by British otologists two very important papers on this subject—by Dan McKenzie in 1931 and Tumarkin in 1938. McKenzie challenged the hypothesis of immigration and Tumarkin dealt it the death-blow.

McKenzie's paper (1931) was read in this Section, a patient marshalling of all the facts and hypotheses known to him on the subject, written in his characteristic and delightful style. He denied the origin of cholesteatosis in the growth into the middle ear of meatal epidermis. He believed that cholesteatosis had a tympanic origin, and after a full discussion he came down on the side of an epidermoid origin. It is suggestive, however, that he had doubts on the subject when he interpolated the passage on " An Objection to the Epidermoid Theory", on the ground that intracranial epidermoids are among the rarest of tumours, whereas aural cholesteatosis is quite common.

It is of more than passing interest to record, as Tumarkin has done, that the President of the Section, A. R. Tweedie (1931) said in the discussion, that he had never been able to accept the theory that cholesteatoma had an embryonic origin, or that it was due to an invasion of the skin of the outer meatus. It was his opinion that the process was dependent upon some past sepsis, often not demonstrable, and that the irritant effect of this on the lining of the antral cavity and mastoid cells, led to an accumulation of an abnormal desquamation. These factors would be sufficient to account for such formations if associated with the one other factor required, a "bottle-neck" cavity. Lowndes Yates also pointed out that the desquamation of the mucous membrane of the middle ear, in cases of inflammation of the middle ear not associated with cholesteatoma, was well recognized, occurring in streptococcal infections more commonly than in staphylococcal infections. He made the point that it did not require a high flight of imagination to postulate desquamation in sheets from infected mucosa, particularly if the infection were caused by streptococci.

In 1938 Tumarkin, gathering together the known evidence, emphasized in his downright way the two major points of importance in the unravelling of the pathological skein. The first referred to the tympanic mucosa, and the second to the defective pneumatization characteristic of cholesteatosis.

Tumarkin pointed out that the middle-ear mucosa was not the same throughout this cavity. The tympanic mucosa was said to be covered by ciliated epithelium, the epitympanic or attic was covered by squamous. The process of enclosed desquamation from the attic pavement epithelium being a strong possibility under certain conditions, it became

unnecessary to postulate a source of desquamation outwith the middle ear. Epithelial ingrowth from the meatus, through a defect in the drumhead, was not required to produce cholesteatosis. In addition, since the initial perforation was always in the membrana flaccida, this might be held to confirm the fact that it is always the pavement epithelium in the epitympanum which desquamates.

The other point of ætiological importance lies in the pneumatization of the mastoid process. It has long been recognized that the mastoid process in the great majority of cases of cholesteatosis shows defective pneumatization. Tumarkin quotes Wittmaack in saying "For many years we have not seen cholesteatoma in a well-pneumatized bone. Even if we do not find a completely compact bone, still there is a very marked reduction of air-cells." Day states, also in support of Wittmaack, that in most cases of cholesteatoma there has been a lack of pneumatization in the mastoid. He says also that the occurrence of cholesteatoma is largely dependent on the altered mucosa of the middle ear, and that a sclerotic mastoid is the result of maldevelopment, not of cholesteatoma. Nilsson (1948) gives the following figures of normal pneumatization in cases of cholesteatoma—Gaben (1936) in 327 cases of cholesteatoma 0·3%, Steurer (1937) in 400 cases, 0·25%, Wustman (1942) in 448 cases, 0·2%. The figures are strikingly similar at 0·2% to 0·3%.

It may be assumed then, that faulty pneumatization is at least associated with, if not directly causal of, cholesteatosis. J. P. Stewart (1928) in a paper on the "Histopathology of Mastoiditis", has contributed much that is of interest in the development of the mastoid, and I take the liberty of quoting him extensively. According to Stewart, the mastoid takes shape only from the start of the second year onwards. Its development may be divided into three periods. The first is the development of the lumen of the recessus and antrum, which takes place in the first year of life. The second period is the development of the pneumatic cells, which normally takes place during the second or third years of life, at least up to the end of the fourth year. If, after the fifth year, the mastoid process is incompletely pneumatized, disturbance of the process has occurred.

The process of pneumatization is as follows: The ingrowing epithelial sac presses upwards, opening up the antral region, the pressure of the growing processes setting up a collateral œdema whereby the parenchymatous element of the bone marrow atrophies, leaving only its framework of endosteal tissue. This becomes myxomatous and is later transformed into loose fibrous tissue which then becomes pressed into a very fine layer on the osseous trabeculæ. It is surmounted by a single layer of flattened epithelium. Simultaneously, widening of the bony walls of the pneumatic cell takes place either by osteoclasts or by perforating vessels. The third period of the development is the further distribution of the pneumatic cells in later life. There are comparatively few completely pneumatized mastoid processes—Ruttin gives about 25% as his figure, and all types may be met with between the completely cellular and the densely sclerotic. Arthur Cheatle states that 15% of mastoid processes are of the acellular type, and 2% of the densely sclerotic type.

Arrested Pneumatization

The normal pneumatization of the mastoid process may be interfered with at any stage of its development by the pressure and effects of local inflammation. Wittmaack has said that in the presence of disease, new connective tissue is formed beneath the epithelial layer of the advancing sac. Consequently, adhesions are formed and growth of new bone takes place, encapsulating the antrum from the spongy mastoid, and so by a mechanical process further pneumatization is prevented. The adhesions form loculi in which the inflammatory processes may continue though in a quiescent form. Staphylococcal infection seems to favour the chronicity and the slow course of the condition.

Stewart states that air plays a very important part in the absorption of exudate from the middle ear, and the exclusion or absorption of air renders the individual more liable to local disease. This is well seen in children where the air content of the middle-ear cleft is very small, and in the incompletely pneumatized mastoid where air may be either excluded or more quickly resorbed. Where blockage of the eustachian tube occurs œdema *ex vacuo* results. The muco-endosteum which normally is pressed flat against the bony wall of the cell, or of the attic, expands to many times its original thickness. The endosteum is spread out into a loose network, according to whether it has been healthy hitherto, or has been the seat of prior infection. Owing to the decreased tension of the supporting tissues, the vessels dilate and extravasation of plasma occurs. When the supporting tissue of the blood vessels consists of well-formed fibrous tissue, the œdema will not be so intense, as the tension will be better maintained. The patency of the eustachian tube has therefore a bearing on the course of local inflammatory disease, in ventilating the cavities of the middle-ear cleft, and in furthering the resorption of serum.

The presence of inflammation, then, or of hæmorrhage, in the middle ear during the first two years of life may prevent pneumatization, and the same pathological process of sepsis may form an adhesive process narrowing the lower inlet of the epitympanic space. This condition may remain completely quiescent for a long period until a local pathological state causes shutting off of the attic. This, in the characteristic state, may be only a very mild catarrhal condition which sets up only minor local danger. The infective agent may be of a type of low virulence, and desquamation of the attic mucosa starts within an intact membrana flaccida. This is shown clinically by dulness of hearing, quite commonly without pain, later by reddening and fullness of Shrapnell's membrane. This may continue for weeks before perforation of this membrane takes place with, usually, very slight discharge which may indeed be shown only as a crust on the drumhead with, however, a purulent underside, observable only on removal. The discharge early becomes malodorous. In time, the perforation becomes definite, there may be a vegetation at the edge of the defect, and the discharge contains squames.

One may envisage the type of case, however, in which the growth of cholesteatosis is so gradual that the membrana flaccida may not be opened, but in which the cholesteatosis may continue to grow and to attain considerable size before becoming a clinical entity. Recently, Riccibona (1948) has reported a case, which he describes as congenital cholesteatoma. A woman of 70 was admitted to hospital unconscious and died. Facial paralysis of old standing was present. She had been unconscious for seven days prior to admission. At autopsy, meningitis was found with a large cholesteatoma between the dura mater and floor of the middle fossa. The membrana tympani was said to be intact and the claim has been made that the cholesteatoma was congenital. It is possible that the growth in this case may have started as indicated above, but of course in the absence of clinical data this must remain an unsatisfied hypothesis.

The middle-ear cleft in infancy appears to be particularly prone to pathological change. The more horizontal slant and the relatively wide calibre of the eustachian tube in the infant tend to place it in greater danger by the canalizing of infection, vomitus, and even hæmorrhage into the middle-ear cleft. The early presence of adenoids must be a very important cause of sepsis in the small cavity of the infant nasopharynx. The presence of adenoids in the first few months of life as a clinical fact is not uncommon. In addition, the association of suppurative otitis media and infantile enteritis is too well known to require more than a mere mention.

It may not be out of place to consider here whether the shape of skull associated with the so-called adenoid facies may not be an important causal factor in nasopharyngeal sepsis leading later to cholesteatosis.

Members will recall the arresting quotation from Hippocrates which used to appear in StClair Thomson's earlier editions—"Those who suffer from headaches and running ears, have high-arched palates and irregular teeth." It is not necessary here to probe far into this question. We do accept, however, that in the adenoid facies, or more properly, the facies of nasal obstruction, there is a very marked tendency to the growth of post-nasal adenoids and sepsis which may later be associated with suppurative sinusitis and sometimes with bronchiectasis. It is many years since one noted the very high incidence of exaggerated adenoid facies among those who suffered from intracranial complication of suppurative ear disease. Naturally a high percentage of these were secondary to cholesteatosis. In these thirty years of the practice of otology I have seen very many instances in which there were several cases of cholesteatosis in two or three generations of one family. The adenoid facies was familial in these cases.

Within the past six months, I have dealt with a case of cholesteatosis from almost the earliest possible clinical existence.

A. C., a nurse aged 23, became suddenly hard of hearing in her left ear in February 1949. There was no previous history of ear trouble save earache in childhood. The patient was in hospital at a distance from her home, and as a result she was in the hands of three different otologists of standing. The condition was thought to be due to a recent acute catarrhal otitis—though there was no history of pain. Reddening of the membrana flaccida became apparent with, later, a minute defect in this part of the drumhead and occasional leakage. The hearing deteriorated further. The patient felt no upset save her hearing defect. The discharge increased, the perforation became more apparent as such, and a small granulation presented. At length there was complaint of pain, five months after the onset of the first complaint. The mastoids were X-rayed, and the right or healthy ear was found to be normally pneumatized, the left being acellular.

In August operation was carried out. As I like plenty of elbow room in operating upon the mastoid the conservative mastoid operation was done, our more convenient name for transmastoid atticotomy. A careful dissection of the upper half of the mastoid and removal of outer wall of aditus and attic showed a small cholesteatosis filling the attic and aditus and extending into the antrum, pushing a

small granulation ahead of it. The long process of the incus was diseased, and the incus was lying partly mobile. The head of the malleus was removed along with the cholesteatosis. The result has been satisfactory, the ear being now dry.

Early recognition of this condition is essential. In my experience, palliative treatment is of value mainly where the hearing remains good, as it does for a time in a limited number of cases. Most cases require operative interference to ensure the drainage and aeration necessary to successful healing.

Mr. F. McGuckin said that microscopically there seemed no distinction in kind between the preponderantly granulating otitic lesion and that which chiefly exhibited a desquamating keratinizing change. All grades could be found, and the same middle-ear cleft might include both extremes in different parts. It was difficult to explain the solid, clean, dry cholesteatomas varying from the tiny sterile "anterior attic bomb" to a massive involvement of cells and cavities throughout the cleft and even through the tip. He did not understand these lesions ætiologically, and was not fully satisfied that they were wholly infective in origin. Moreover, he remained mystified as to the precise mechanism by which these masses caused such clean, smooth bony erosion—if in fact they were the eroding agent.

He considered that cholesteatoma could be found in cellular bones, sometimes highly cellular, and that in rare cases each cell might be found to contain its own separate cell mass, the pathology extending occasionally as far as the internal auditory meatus. With respect, therefore, he differed from the President's statement that cholesteatoma was found in a bed of hard bone. This was the common but not the invariable finding.

Mr. E. Watson-Williams wondered whether "cholesteatosis" was a happy word. Was the reference to a process or to a mass? They had been accustomed to giving the name "cholesteatoma" to a lump of material and "cholesteatomatosis" to the process of its formation. He felt that the use of the word "cholesteatosis" was likely to present difficulty to many people. "Osis" = process: but now a word ending in "osis" was being used not for a process but for a visible mass.

As to the actual condition, he thought that whatever one's views, one had to take into account, as the President had emphasized, the common association between the acellular mastoid and the cholesteatoma. His own experience was that cholesteatoma was not encountered, or was very rarely encountered in a mastoid, save in cases in which the cells had not developed. His view had been for many years that the acellular mastoid was due to the early arrest of pneumatization and not to sclerosis causing obliteration of the cells which had in the past come into existence. He found it impossible to believe that a pneumatized mastoid could become sclerotic.

But his experience differed from that of the President in respect to the position of the perforation. He thought that the President's point was that the perforation in the case with a cholesteatoma was in the membrana flaccida. In many cases the perforation was in the membrana tensa; but there was a small group in which the space of Prussak became involved and a cholesteatoma emerged there, perhaps destroying the outer wall of the attic and the head of the malleus without, as a rule, affecting the hearing, and quite often without involvement of other parts of the middle-ear tract—a rare and isolated state of affairs. His own view of the cause was that it was always inflammatory. He could not envisage a congenital cholesteatoma. It was so constantly associated with inflammation that he thought that in those cases which were said to have arisen *de novo* without inflammation there must be an inadequate history.

Mr. D. A. Barley said that on this question whether cholesteatoma could occur in an extensively pneumatized mastoid he would like to describe a case. This was of a boy aged 3, who in March 1948 had a history of one week's discharge from the left ear. Its onset was insidious and there was no apparent pain or deafness. Examination showed a posterior marginal perforation of the left drum, offensive discharge and infected tonsils and adenoids, which were removed a few weeks later. Radiological examination showed both temporal bones to be extensively pneumatized. Cells on the left side were uniformly clouded, indicative of infection. Conservative treatment failed to arrest the discharge.

Six months after the disease was first noticed the left mastoid process was explored and an extensive cholesteatomatous deposit found within the left temporal bone. This extended from the tip of the mastoid well into the root of the zygoma. All three semicircular canals, the dura mater and the canal of the facial nerve together with the lateral sinus were exposed. The interesting thing was that the pneumatization patterns of both temporal bones were identical. As the right drum showed a small area with thickening just behind the short process of the malleus it was thought justifiable to explore the right mastoid process in order to exclude the presence of any primary cholesteatomatous deposit. This was done but no cholesteatoma was found in the normally pneumatized right temporal bone. It would be interesting to see, in view of the abnormality of the right drum, whether cholesteatoma would form within what was known to be a normally pneumatized mastoid process. Diamant had published a paper in which it was suggested that marginal perforations might result from primary cholesteatomatous deposits. It seemed incredible that in a child of 3 this cholesteatomatous deposit could result from a marginal perforation with so short a history.

REFERENCE

DIAMANT, M. (1948) *Arch. Otolaryng., Chicago*, **47**, 581.

Mr. Donald Watson said that some years ago, shortly after Dan McKenzie's paper, he saw a child of 7 with a cleft palate and harelip, who was very ill with a right-sided acute mastoiditis and meningitis. In her convalescence she had symptoms of brain abscess, but fortunately this was cerebral œdema and she recovered without intervention. At operation a cholesteatoma was found in the right mastoid. As she had been so ill the parents insisted that the child should come and see him (the speaker) regularly. About eighteen months after the first operation she complained of deafness in her left ear, and making a further examination he found a tiny scab in the region of the attic. He picked it off and it had the appearance which the President had described. Later he had to do a modified radical operation on the left ear where a cholesteatoma was found also. The child had never had earache and there was no history of otitis media. These were undoubtedly primary or "congenital" cholesteatomata on both sides in a child with a cleft palate and harelip.

Dr. Hugo Frey said that he had seen a primary cholesteatoma of the middle ear. Primary cholesteatomata, well known to the pathologist, were found in various bones of the skull—temporal, frontal, occipital—and were considered to be due to primary displacement or disarrangement of the epithelial germs. Then there were cholesteatomata which were secondary to chronic middle-ear suppuration. In addition there was another class, the primary cholesteatoma in close association with the tympanic cavity, and yet having no actual connexion with the cavity itself. He had seen such a case in a patient 50 years of age. The operation which he undertook revealed a cholesteatoma, half the size of his fist, occupying a large part of the posterior fossa. The tumour had eaten away the upper part of the temporal bone but had not entered the middle-ear space. It had made its way to the surface through the posterior wall of the meatus. The case was published many years ago; and since then he had seen in the literature other cases quoted every few years. He had no doubt that such primary cholesteatomata did exist, quite apart from middle-ear suppuration.

Mr. C. S. Hallpike said that he thought this still difficult subject was now capable of considerable clarification. It was quite true that in the temporal bone one did encounter a number of epithelial tumour-like masses, which had nothing to do with the middle ear at all and which were, on the whole, curiosities of otological practice. What was left were these other epithelial masses, which always arose from the middle ear. The notion that they necessarily arose at some time from the external ear was, he would have thought, quite discredited. In the course of examining histological preparations of the temporal bone he had encountered in the attic little masses of epithelial material unaccompanied by any evidence of suppuration or by perforation of the tympanic membrane, and on one or two occasions he had seen in such cases, without deafness or perforation, large cholesteatomata filling the attic. These, he would have thought, were without doubt an early stage of the attic cholesteatoma with perforations with which they were so familiar. This condition arose in the middle ear and should be called middle-ear cholesteatoma.

The question which remained was whether it should be considered primary or secondary. He did not think there was very much to discuss on that point. Something must cause this proliferation of epithelium and therefore it was secondary.

As to the cause itself, it was most likely from what they knew of faulty mastoid pneumatization, that this region of the middle ear was irritated and caused to proliferate by some infection in early childhood or by some defective aeration of the middle ear, as the President had suggested.

Mr. G. Ewart Martin said that when he had been associated with the President during the period they had both worked with Logan Turner and J. S. Fraser many more cases of cholesteatoma were seen than nowadays. The number described as cholesteatoma was very large and there was no doubt that the flattened squamous cells in the attic proliferated, but was this proliferation due to infection or to something else? He felt there must be a cause and therefore these cases were not really primary but were secondary to something.

In recent years there were more such cases because of the routine examination of school children. He recalled that during the last war a man was examined and his hearing tested and passed as normal by the Medical Board. There was no history of pain in the ears at any time and examination at the Medical Board with an otoscope revealed nothing abnormal. One week later he reported with facial weakness on one side and constant headache. On examination there was a slight fullness of the attic.

It was decided to open the mastoid and the first blow of the chisel on the mastoid process brought everything away. There was the typical odour of cholesteatoma and examination proved this to be present. There must have been an infection of the lower part of the attic.

He was certain that a number of these cholesteatomata were associated with posterior marginal perforations which would again suggest differences in ætiology. He recollected one case in which a collection of cells in the attic became infected, and another with a chronic infection and a secondary proliferation with the characteristic smell and appearance.

Mr. I. A. Tumarkin said that he had not changed his opinion during the years since he wrote his original paper, which he would summarize as follows: There is only one type of normal mastoid, namely, the completely pneumatized. The so-called sclerosed mastoid is really non-pneumatized—i.e. it has failed to develop the normal air-cell system. The most important cause of this failure is latent mastoiditis associated with gastro-enteritis in nurslings. In this condition, the mucous membrane of the tympanic cleft has become in some way devitalized and so, in later life, is predisposed to break down under the impact of an infection.

There are two types of middle-ear mucosa—the tympanic mucosa covered by ciliated epithelium, and the epitympanic covered by squamous epithelium. These two types behave in different ways. The ciliated epithelium gives rise to the mucopurulent type of otitis media, often associated with nasopharyngeal disease. The squamous epithelium tends to proliferate and form squames. These squames are responsible for all the different pathological conditions found in the chronically infected mastoid. When the process is extremely slow it produces the so-called primary cholesteatoma, a laminated, pearly encysted mass.

At the other extreme—with active infection—bone destruction with formation of granulations and polyps is found. A more copious exudate occurs and this has two consequences. Firstly, the drum is perforated and secondly, the squames never have time to organize into typical laminæ. At most a whitish detritus is found. This is the condition which the President has so aptly designated Cholesteatosis and it accounts for all the conditions under discussion. It is always possible at operation to find some degree or other of cholesteatosis and often a mastoid exhibits different stages in different parts.

In acute suppurative otitis media, there is a stage *before* the drum perforates and a stage after perforation. These are not two separate entities—they are merely stages in a single pathological process. Similarly the existence or not of a perforation with overt discharge does not justify the description of primary or secondary cholesteatoma as separate entities.

Mr. I. B. Thorburn wished to suggest a practical clinical classification for these cases which he personally had followed in trying to design suitable operative treatment for them. There was a type of cholesteatoma which seemed to invade widely through the middle ear and mastoid space, and for that type one had to resort to a meticulously thorough mastoid operation. There was another common type where with the help of magnification it could be seen that the tympanic cavity had successfully walled itself off from the disease, either by granulation tissue or by new membrane formation. In such cases there could be an intact ossicular chain and a functioning tympanic membrane even though the head of the malleus and part of the incus were destroyed. A radical mastoid operation was not indicated but an epitympano-mastoidectomy would control the disease and give a much better functional result.

Miss Winifred Hall said that she had never felt very happy about the theory that non-pneumatization of the mastoid was due to a developmental failure. That was merely begging the question. Bony sclerosis was the response to infection, and infection in the infantile mastoid could occur so early—even in the first week or two of life, be so transient, and disappear without leaving any outward sign of its occurrence. One should not ignore the possibility of an unobserved or forgotten infection being the primary cause of a sclerotic bone. Having seen several hundreds of infants with otitis media, she thought this the most likely explanation both of so-called failure to pneumatize, and of so-called primary cholesteatomata.

She could not agree with the statement that the mastoid process and air cells were not fully developed before 2 to 3 years of age—this is disproved by operative findings which commonly show at all events partial pneumatization at 2 or 3 months of age, while complete pneumatization has been seen by 7 months. The process itself is present, though small, at birth.

Referring to established cases of cholesteatoma, Miss Hall commented on the frequent failure of radiological examination to help in diagnosis, particularly of early cases.

The President, in replying to the discussion, said that the question had arisen as to the bilateral occurrence of this condition. Of course it was quite commonly bilateral. They must all have seen many cases in which bilateral cholesteatosis was present. A diffuse cholesteatosis was quite commonly met with.

As to Mr. Watson-Williams's point about the etymology, he thought it was quite legitimate to think of the condition as a process, a continuing process, and the suffix "osis" would bear such an interpretation.

Clinical Section

President—W. A. BOURNE, M.D.

[*October* 14, 1949]

Sternal Secondary Deposit of Breast Cancer Treated by Radium Implantation. Patient Well Twenty-four Years Later.—W. SAMPSON HANDLEY, M.S.

Mrs. R., now aged 82.

Was operated on for left breast carcinoma by Miss Aldrich-Blake in 1918. In 1925 a prominent swelling 2½ in. in diameter appeared over the junction of the first and second pieces of the sternum and Dr. Helen Chambers referred her to me for radium treatment. Six tubes of radium bromide totalling 275 mg. were implanted in a circle round the swelling, and tubes of 50 and 25 mg. in its soft centre, for twenty-four hours. Within a few weeks the swelling disappeared, and pain ceased. Telangiectases appeared over the treated area. In 1943 a small skin nodule in the area was successfully treated by X-rays by Dr. D. W. Smithers. I am indebted to him for an X-ray showing recalcification of the softened sternum (Fig. 1).

At present, October 1949, this lady is perfectly well, and her voice may occasionally be heard on the radio.

FIG. 1.—Radiograph taken by Dr. D. W. Smithers in 1943, showing recalcification of the upper part of the sternum, indicated by the arrow. The lower part of the sternum shows some senile rarefaction but its outlines are well defined and anatomically normal. There is calcification of some of the costal cartilages.

Dr. G. E. Vilvandré said that the present result in this case was obviously excellent.

The action of stilbœstrol in these cases was worthy of discussion, and I have seen some cases and others have been described by Dr. Connell of Liverpool where bone recalcification had taken place to an extraordinary amount in ribs, humerus, pelvis, which had previously been studded with cancerous growth. Pain had ceased and general improvement followed.

One of the earliest sites of secondary deposits from the breast was in the pelvis, especially in the rami of the ischium. Patchy translucence of varying degree revealed secondary deposits and in carcinoma of the breast the pelvis should always be X-rayed.

A Dysplastic Lymphangiectatic Condition of the Left Hand and Forearm and Right Foot and Leg of a Little Girl, with Enchondromata or Cysts in Phalanges of the Affected Extremities.—Surgeon Commander M. A. RUGG-GUNN, R.N., M.D.; W. W. WOODS, M.R.C.S., L.R.C.P.; and F. PARKES WEBER, M.D.

M. R., a Singhalese girl, aged 4½ years. Normal birth.

Was brought in June 1949 as an out-patient to the Royal Naval Hospital, Trincomalee, Ceylon, because of a peculiar enlargement of the left upper limb and the right lower limb from the elbow and knee downwards. According to the parents this enlargement was present at birth and since then has increased only in proportion to the general growth of the body. At about the fourth month a vesicular eruption appeared on the affected parts; this disappeared, but has reappeared for periods of a few months at a time ever since; there is no accompanying itching. There is no parental consanguinity, nor is there any relevant family history, especially in regard to deformities. The child is the youngest of three girls, one boy having died at 4 months of pneumonia. The mother had one miscarriage.

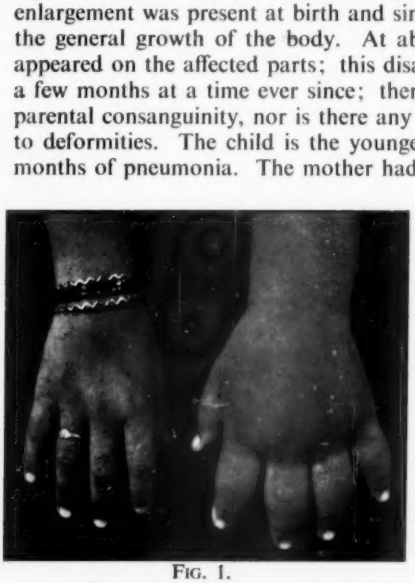

FIG. 1.

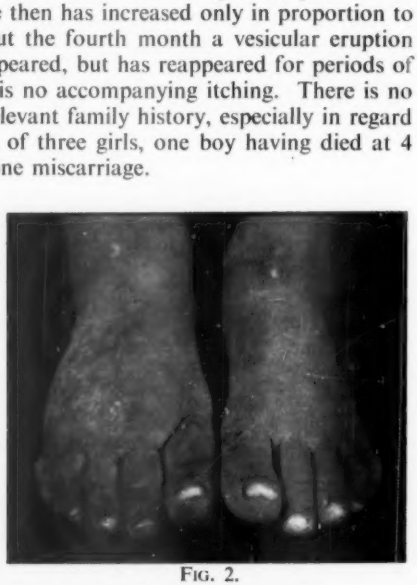

FIG. 2.

FIGS. 1 and 2.—Photographs showing the appearance of the affected extremities.

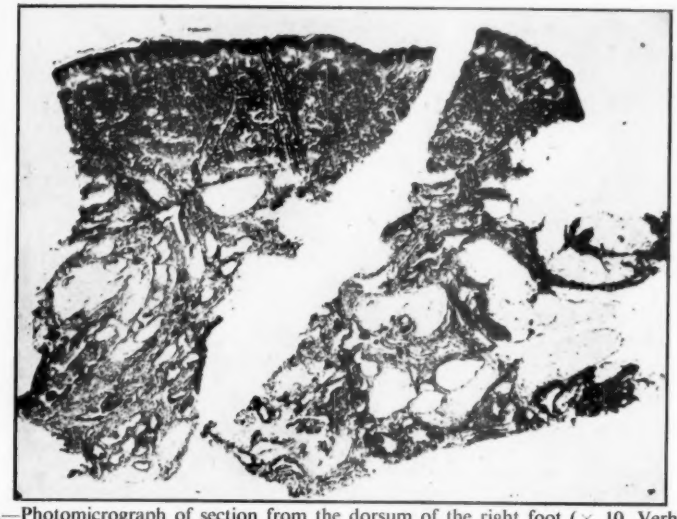

FIG. 3.—Photomicrograph of section from the dorsum of the right foot (× 10, Verhoef stain), showing widely dilated lymphatics and fibrosis in the subcutaneous fat. In the subepidermal part of the dermis are some slightly dilated lymphatics.

Present condition.—In the enlarged portions of the limbs (*see* photographs), by inspection, palpation and X-ray examination, the enlargement is found to be confined to the soft parts; there is no pitting on pressure (no œdema) and no discoloration of the skin beyond that which is connected with the occasional vesicular eruptions. There is apparently no difference in length of limbs, nor is there any noticeable difference between the radial pulses. Skiagrams show the presence of multiple enchondromata or cysts in some of the phalanges of the affected limbs; the rest of the skeleton is normal. General examination of the whole body shows no evidence of any other abnormality; no suggestion of sarcoidosis or xanthomatosis, though the blood serum cholesterol was high, namely, 500 mg.%. No enlargement of liver, spleen or superficial lymph glands. Blood count: Hb 92%; erythrocytes 4,520,000; C.I. 1·0; leucocytes 7,400 (polys. 40%, lymphos. 54%, monos. 3%, eosinos. 3%). Blood urea: 30 mg.%. Blood serum calcium: 8 mg.%. Urinalysis showed nothing abnormal. Wassermann reaction negative. The general health appears normal.

FIG. 4.

FIGS. 4 and 5.—Skiagrams showing enchondromata or cysts in some of the phalanges of the affected hand and foot. (*See* overleaf Fig. 5.)

In a specimen excised from the dorsum of the right foot Mr. W. W. Woods reports that there is conspicuous dilatation of lymphatics in the subcutaneous fat; some of the lymphatics have muscular walls; there is pronounced fibrosis, with elastosis, in the subcutaneous fat; there is neither œdema nor inflammatory infiltration in the subcutis or dermis; in the subepidermal part of the dermis are a few slightly dilated lymphatics.

Remarks.—There can be no doubt that the condition is a developmental (congenital) lymphangiectatic dysplasia of the affected parts (without œdema). This diagnosis is

endorsed by Dr. W. Freudenthal. The occasional vesicular eruptions are perhaps connected with the subepidermal dilated lymphatics. The multiple cyst-like appearances in some of the phalanges of the affected hand and foot (a biopsy was impossible) are most probably due to enchondromata. An analogous condition of hæmangiectatic dysplasia of extremities is sometimes associated with enchondromata (? cartilaginous hamartomata) of the Ollier type of dyschondroplasia, constituting the so-called Maffucci's syndrome (*see* Carleton, Elkington, Greenfield, and Robb-Smith, *Quart. J. Med.* (1942) **11**, 203).

Dr. G. E. Vilvandré, when asked the condition of the terminal phalanges and metatarsals, suggested that they were most probably numerous enchondromata.

Dr. A. Elkeles said that the cystlike appearances in the phalanges, as seen in the radiographs of hands and feet could be interpreted as enchondromata. The phalanges were notably affected in this type of dyschondroplasia. Dr. Parkes Weber was able to exclude sarcoidosis and xanthomatosis in which similar radiological bone changes might occur. Some years ago he had observed an extensive hæmangioma in a child, affecting one lower arm, wrist and hand. Radiographs of this region showed concomitant involvement of the bones by hæmangioma. In the present case the cystlike bony lesions were also confined to the areas affected by lymphangiectatic dysplasia. Since the basic pathology of hæmangiectatic and lymphangiectatic dysplasia was similar, it might be suggested that the cystlike lesions in the phalanges of the present case could also be explained as an extension of the lymphangiectasis of the surrounding soft tissues.

FIG. 5.

Mr. A. Dickson Wright said that there was a close similarity between the behaviour of the lymphatics and the veins in the matter of congenital deviants. The compact lymphangioma of the neck resembled the circumscribed angioma and in the arms and legs there occurred diffuse lymphangiomata resembling those of Weber's disease except in the contents of their spaces. It would be interesting if this case showed that in the formation of enchondromata of the phalanges there was a still further analogy in the two diseases.

FIGS. 4 and 5.—Skiagrams showing enchondromata or cysts in some of the phalanges of the affected hand and foot. (*See* Fig. 4 on previous page.)

Diffuse Adenomatosis of the Trachea.—J. A. TUTTON, M.B., B.Chir. (for N. LLOYD RUSBY, D.M.).

G. C., male, aged 54. Labourer.

History.—Cough with 1 oz. of mucopurulent sputum since 1933 following pneumonia on the right side. January 1944: Hæmoptysis whilst at work. Since then has had attacks of hæmoptysis every two or three months. June 1949: 10 oz. hæmoptysis. For four years has had dyspnœa on exertion. Weight: For the last ten years weight has been steady at 10 st.

Past history.—Left antrostomy in 1930 for hæmantrum following repeated epistaxis.

Past investigations.—Bronchoscopy 1945: ? Tuberculous tracheobronchitis. (Description corresponds closely to present appearance.)

On examination.—Apyrexial. Diffuse nævi over face and trunk. Two polypoid angiomata on chest. Otherwise general physical examination revealed no abnormality. Blood pressure 140/95.

Investigations.—X-ray of chest—cystic condition right upper lobe confirmed by tomography. X-ray of sinuses clear.

Laryngologist's report.—"No cause for bleeding found in upper respiratory tract. Lesions well seen in trachea with laryngeal mirror."

Sputum persistently negative for tubercle bacilli and neoplastic cells. Full blood count normal including clotting and bleeding times. W.R. negative.

Bronchoscopy (30.9.49).—Cords normal. Trachea normal until about two-thirds of it had been inspected when the mucous membrane became hypertrophic and the change was apparent on both sides, left more than the right, and was continued into both main bronchi and appeared to terminate rather abruptly on the left side at the left upper lobe, but rather less abruptly on the right side at the right middle lobe level. The craggy rugose appearance suggests a condition of diffuse papillomatosis.

No bleeding was excited. Mucosa was more injected than normal. Biopsy taken. *Section* shows normal mucous membrane.

The most likely diagnosis in view of intact mucous membrane is of a diffuse adenomatosis of the trachea.

The association with repeated epistaxes, hæmantrum and angiomata of skin is interesting. It is possible that the circular shadow seen in the right upper lobe may be the remains of a blood cyst.

Fibrocystic Disease of Pancreas. Bilateral Bronchiectasis. Cirrhosis of Liver.—D. GERAINT JAMES, M.R.C.P. (for J. W. CROFTON, M.R.C.P.).

G. R., page boy, aged 15 years.

Previous history.—Frequent chest colds each winter since age of 3 years. Aged 9 years: In hospital for tooth extraction—enlarged liver noted. Weight 3 st. 7 lb. Aged 11 years: Illness (? jaundice) with pale stools, since when stools have continued to be pale and offensive, and he has failed to grow or to develop. Since this time chest colds have been more severe. Aged 14 years: Clubbing of fingers noted by

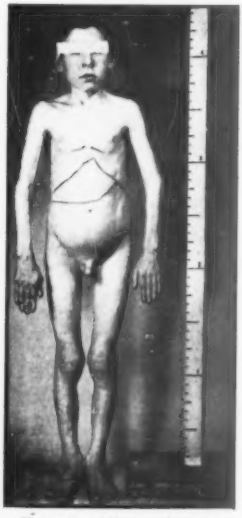

FIG. 1.—Illustrating lack of growth and genital development, enlarged liver and clubbing.

FIG. 2.—X-ray of chest, showing "snow-flake" mottling of both lung fields.

school nurse. Aged 15 years: Five months ago, severe bronchitis with purulent sputum and marked dyspnœa.

Family history.—Father and mother well. 1 brother died of bronchopneumonia, aged 2½ years.

On examination.—Looks 9 to 10 years old. Ht. 4 ft. 4 in. Wt. 3 st. 10 lb. No signs of puberty (Fig. 1). Very cyanosed, and quite marked clubbing. Looks ill ; markedly dyspnœic; and febrile. Chest, fixed, with Harrison's sulci. Harsh breath sounds with numerous added sounds throughout both lung fields (Fig. 2).

C.V.S. N.A.D.

Abdomen: Enlarged liver, 4 fingerbreadths below costal margin in mid-clavicular line, firm, not tender. No splenomegaly. Both testicles undescended. No pubic hair.

Investigations.—Hb 100%; W.B.C. 16,000. E.S.R. 72. Serum bilirubin 1·1 mg./100 c.c. Plasma proteins 7·7 grammes %. Albumin 3·1 grammes %. Globulin 4·6 grammes %. Thymol turbidity 2·5 units. Colloidal gold 0. Blood calcium 11·1 mg.% Serum phosphate 4·7 mg.%. Chest X-ray shows diffuse "snow-flake" mottling throughout both lung fields. Ossification centre for trochlea not yet present. No evidence of rickets. Sputum showed mixed bacterial flora, including *Strep. viridans*, Neisseria, diphtheroids. Mantoux negative 1 : 100, old tuberculin. Duodenal intubation performed; juice showed absence of trypsin. Stools putty-like. On standard fat balance of 50 grammes intake daily for four days, fæcal fats (daily average) were 13·8 grammes. This shows 73% fat absorbed. On diet of 100 grammes protein daily, there were 2·2 grammes of nitrogen in the fæces daily, and 5·4 grammes of nitrogen in the urine daily. This showed a protein absorption of 89% and utilization of 50% protein.

Progress and treatment.—The severe pulmonary infection was controlled by 1,000,000 units of penicillin intramuscularly daily, and also inhalation penicillin.

The diet was increased to a highly nutritious diet with added vitamins, with a resulting weight gain of 6 lb. in the first month, and his general condition immensely improved.

Dr. J. W. Crofton: The absence of duodenal trypsin is strong evidence that the case is one of fibrocystic disease of the pancreas. It is unusual in that the boy has survived to the age of 15 and that there was no clear evidence of disability before the age of 3. He has so far reacted well to dietetic treatment and to penicillin treatment of the purulent bronchitis.

Toxic Thyroid Adenoma. Generalized Osteoporosis with Collapse of Some Vertebræ.—B. GOTTLIEB, M.R.C.P.

B. V., spinster, aged 47. Housekeeper.

Menopause at 42 years.

Admitted St. Mary Abbots Hospital 30.3.49. Discharged 9.5.49.

History of thyrotoxicosis.—Thyroid gland enlarged for at least thirty years. Disliked warm weather for many years. Nervous and excitable at least eighteen months. Lost 2½ st. in weight past three months. Shortness of breath on exertion with œdema of feet two months. Vomiting three weeks.

On examination.—Weight, 8 st. 4 lb. Heart rate 104, extrasystoles. Tremor of fingers. Large thyroid adenoma involving right lobe and isthmus.

Investigations.—1.4.49: B.M.R. + 65·6%. 5.4.49: Radio-active iodine test—4·7% excreted in forty-eight hours. 1.4.49: X-ray chest—retrosternal prolongation of thyroid.

Treatment.—16.4.49 – 9.5.49: 400 mg. methyl thiouracil daily. 9.5.49 – 2.6.49: 200 mg. methyl thiouracil daily.

The methyl thiouracil was given preparatory to thyroidectomy, but patient declined operation subsequently.

Progress.—Thyrotoxic symptoms and signs lessened.

Gained 1½ st. in weight. B.M.R. 2.9.49: + 13·5%.

History of osteoporosis.—Ten years back felt "weak and cold" at times following exertion.

End of June 1949 (after control of thyrotoxicosis) developed severe pain in back radiating along the left sciatic nerve.

July 1949: Pain lower dorsal spines radiating along right subcostal margin. Pain persistent since then and back has gradually become bent.

Readmitted 24.8.49.

FIG. 1.—X-ray lumbar spines showing osteoporosis with collapse of some vertebræ.

On examination.—Height 5 ft. 3 in. (5 ft. 5 in. one year previously).

No gross thyrotoxic signs. Thyroid adenoma. Heart rate 80, regular.

Spines: Tender lower dorsal and upper lumbar vertebræ. Rigidity of spines. Kyphosis of dorsal spines.

Investigations.—24.8.49: Radiography bones: Generalized osteoporosis all bones especially vertebræ with collapse of some dorsal and lumbar spines (Fig. 1).

Sacro-iliac joint spaces not seen.

16.9.49: Serum calcium 10·1 mg.; serum phosphates 3·8 mg.; and serum alkaline phosphatase 14·5 units/100 ml.

Fæcal fat estimation.—12.10.49: Total fat 7·68 grammes, split fat 7·13 grammes, and unsplit fat 0·55 gramme per 100 grammes dried fæces.

Comment.—The association of osteoporosis with thyrotoxicosis has been frequently reported but Bartels and Haggart (1938) were able to find only 5 cases in literature where the osteoporosis was sufficiently severe to cause spontaneous fractures. Although these conditions may coexist there is no definite evidence that the thyrotoxicosis is actually responsible for the osteoporosis. Several observers have reported no improvement in the osteoporosis despite thyroidectomy and Hunter (1935) found that the negative calcium balance persisted in his case two weeks after thyroidectomy, and osteoporosis was unchanged one year later. In my patient symptoms and signs due to the osteoporosis first became obvious only after thyrotoxicosis was controlled by methyl thiouracil.

The cause of the osteoporosis has not been determined in these cases. Although hyperparathyroidism has been suggested as a possible cause, the serum calcium and phosphorus have not been raised in previously reported cases and they were normal also in my patient. Nor was there any evidence of steatorrhœa in any of these patients.

As regards treatment it is proposed to perform a thyroidectomy on this patient because of marked retrosternal prolongation and to avoid a possible relapse of the thyrotoxicity and to examine the parathyroid glands during the operation. Large doses of vitamin D and calcium will be tried subsequently, although McCance (1947) mentions osteoporosis associated with thyrotoxicosis as being resistant to vitamin D. At the same time an orthopædic appliance will be used to prevent further deformity of her spine.

Meningococcal Encephalopathy.—M. N. PAI, M.R.C.P.

Male, aged 32, single.

1940: Since an attack of cerebrospinal fever he has suffered from defective memory, confusion, loss of initiative, mild "depression", and changes in personality. He has become morbidly passive and docile, timid and has been unable to hold down a job for longer than a few days. On account of long spells of unemployment he has become completely dependent on his elderly parents.

1947–48: For fifteen months in hospital in the Midlands and was treated with electric convulsion therapy without any improvement at time of discharge.

Previous history and personality.—No family history of mental or nervous disorder. According to his school report he was a boy of good intelligence, of good character and was always trustworthy, polite and friendly with his fellow scholars. Prior to the meningitis for nine years he had no unemployment. He had even taught himself several foreign languages.

1949: *Condition on admission.*—Well nourished. C.N.S.: NAD. *Mental state*: Mild euphoria, lack of spontaneity and perseveration; can converse in French, Italian, Polish, Spanish and Hindustani, but gets easily confused. His memory for past events is very defective and he has difficulty in forming new associations of ideas and in planning ahead. *Change in personality*: Previously a good "mixer", well behaved and well mannered, he has now become careless in habits, untidy in dress, diffident and childish in behaviour. Diminished libido, impotence and lack of interest in the opposite sex has been followed by the development of an obsessional urge to interfere with young boys.

Investigations.—Wassermann reaction negative. Electro-encephalogram: "Abnormal. This record suggests a diffuse organic deterioration, mainly in the temporo-parietal areas."

DISCUSSION

The intellectual, social, economic and moral deterioration as well as tendencies to prolonged invalidism present in this patient are prominent features of meningococcal encephalopathy (Pai, 1944, 1945, 1946). This condition is easily differentiated from schizophrenia by the absence of evidence of thought disorder, hallucinations and delusions and from post-contusional states by the absence of irritability, headaches, aggression and paranoid reactions. Neurosis is excluded by the absence of psychological causes and of personal motives.

Torticollis and Tremor of Head of Five Years' Duration. (*Wrongly Diagnosed as Functional in Origin*).—M. N. Pai, M.R.C.P.

Male, aged 61. Long-distance lorry driver for thirty years.

1944: Sudden onset of acute pain in the neck, worse after movements of head and neck. Despite physiotherapy for nine months pain persisted and patient gradually developed right torticollis and an involuntary tremor of the head. Continued to drive a lorry at night.

1948: Tremor of head and neck became incessant and difficult to control; the lower jaw began to droop and he had difficulty in speaking, eating and drinking. On account of the severity of his symptoms, which were still considered functional, he was recommended for urgent in-patient treatment at a neurosis centre.

1949: *Condition on admission.*—Thin, poor physique, looks older than his age. Marked kyphosis with head bent forwards, the chin almost touching the chest wall. The tremor of the head has two components:

(1) Lateral tremor consisting of a quick movement from right to left and a slow release movement in the reverse direction.

(2) To-and-fro or antero-posterior tremor consisting of a slow, strained forward movement and a quick backward recoil.

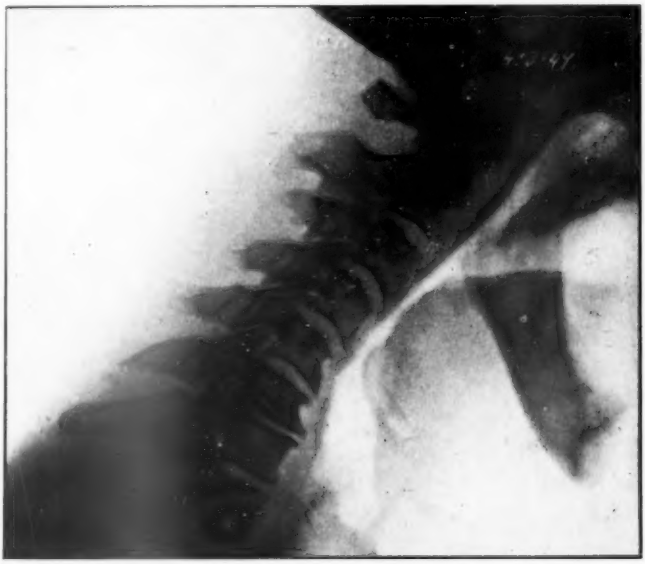

Fig. 1.—Showing advanced osteoarthritis of cervical vertebræ and degenerative changes in the discs, especially between C5 and C6 and between C6 and C7.

Continuous rolling movements of the tongue. Right torticollis and hypertrophy of the right sternomastoid. Hypertrophy and spasm of right trapezius and right semispinalis capitis. Grating audible in the neck and crepitus felt in the region of C5 and C6. Central nervous system: Marked retinal arteriosclerosis, left eye amblyopic, vision being less than 6/60. General medical examination revealed nothing else abnormal.

Investigations.—W.R. negative; total blood counts and sedimentation rates within normal limits. Hb 100%. Colour index = 1·0. X-ray of cervical region: Advanced

osteoarthritis and degenerative changes in the discs between C5 and C6, and between C6 and C7 (Fig. 1). Appearances compatible with an old crush fracture of C6. Sacral region: Osteitis deformans.

Discussion

This patient well illustrates how tremor of the head may be caused by physical conditions. For ordinary activities central vision is essential but for driving any vehicle good peripheral vision is necessary. The greater the speed of a vehicle the greater is the need for good vision. Being almost blind in his left eye he was therefore compelled to bring the right field of vision towards the middle in order to avoid objects moving from his left side. This frequent turning of the face to the left led to hypertrophy of the right sternomastoid. Each time the face was turned to the left the right trapezius and the right semispinalis capitis pulled the head backwards and to the right, since the right shoulder was fixed during driving. These alternate movements led to hypertrophy of the muscles and caused the lateral tremor.

For thirteen years he was on night duty which involved driving in the blackout continuously for ten to twelve hours or longer. This required craning his neck forwards but on account of the pain due to degenerative changes in the vertebræ and discs the head was quickly withdrawn. These two movements resulted in the anteroposterior tremor. In 1944 he apparently sustained a crush fracture of the body of C6.

No adequate explanation of the movements of the tongue can be given. Normally the upper dental arch is wider than the lower so that the upper incisors and canines overlap the lower ones. The opposed dental arches form a strong fortress which protects the surface of the tongue from external damage. In this patient owing to the large size of the mandible the lower dental arch is wider than the upper and he has difficulty in keeping his mouth closed. The movements of the tongue are, perhaps, nature's attempts to protect the surface of the tongue.

Psychiatric investigations have not revealed any psychological factors or personal motives to account for the tremor.

Five cases of Rheumatoid Arthritis: Extraordinary Therapeutic Results by Procaine Injections in Specific Objectively Located "Myalgic Spots."—M. G. Good, M.D. A report of these cases has appeared in *Zeitschrift für Rheumaforschung*, 1950, Vol. 9, Heft 1–2, Jan.–Feb. (in English).

Théophile de Bordeu: An Eighteenth Century Pioneer in Endocrinology

By A. P. Cawadias, O.B.E., M.D., F.R.C.P.

Théophile de Bordeu, the great mid-eighteenth century Montpellier physician, developed in his work all aspects of Constitutional Medicine, and in doing so introduced into medical thought the conception of internal secretions as pointed out by H. Grasset [1], and by Max Neuburger [2]. In this paper I shall endeavour to study more completely the personality of Bordeu, and to show his role in the stream of thought, which from the Hippocratic humoral conceptions brings us to contemporary Endocrinology. This study will help us to consider the principles of Endocrinology, because we cannot understand this fascinating branch of Medicine simply by absorbing the innumerable papers which are being published at an increasing rate. We can read ourselves into ignorance and stupidity if we do not seize the directive lines of scientific thought as shown through history. We have to think of our problems more and more closely with the help of the great intellects that have thought about them in the past. Scientific thinking—the basis of Science—can only be historical thinking.

Life and Background [3, 4, 5]

Théophile de Bordeu (Fig. 1) was born in 1722 and died in 1776. He thus belongs to the mid-eighteenth century, the times of Louis XV in France, and George II in England. His French contemporaries were Boissier de Sauvages, Senac, Lorry, Barthez, Tronchin. Amongst his

Fig. 1.—Théophile de Bordeu (1722–76)

From Rolleston: The Endocrine Organs in Health and Disease, 1936, Oxford University Press.

British contemporaries—a more brilliant galaxy—were Pringle, Heberden, Fothergill, Lettsom, Erasmus Darwin, Withering.

His life can be divided into three phases, that of preparation, the "Wanderjahre", and the Paris period.

The period of preparation (1722–1743) was lived in his native land. He was born at Izeste near Pau, a scion of a great family, and the son of a distinguished physician, Antoine de Bordeu, state councillor, superintendent of the waters of Aquitaine, and one of the pioneers of Medical Hydrology. This Antoine de Bordeu, a cultivated gentleman and keen naturalist, was the first teacher of his son Théophile and developed in him the power of observation and of thinking, accompanying him on his walks and excursions in the beautiful surrounding country. A general, principally classical, education was given to Théophile de Bordeu in the college of the Jesuits of Pau and of the Barnabites of Lescar, and at the age of 17 he entered the medical school of Montpellier.

Montpellier is, with Salerno, the school that introduced Medicine into the West. Although already going strong in the eleventh century, it maintained its supremacy until the beginning of the nineteenth century, and in Bordeu's day was at its zenith with teachers such as the great clinician, Fizes, and the founder of modern Nosology, Boissier de Sauvages. An essential feature of that great school was its faithfulness to the Hippocratic tradition, that is, of the method of clinical observation combined with the cult of general ideas. Montpellier was the real civitas Hippocratica, and even when I was there as a student we could read everywhere "Nunc Monspelierensis Hippocrates". Bordeu applied himself, particularly, to Anatomy, which was in those days the only discipline embodying precise scientific method. He followed the clinical teachers who took the students into the homes of the poor patients—a special method of Montpellier, the real Hippocratic method of clinical teaching—but also frequented the St. Eloy Hospital open to all students. He obtained his M.D. in 1743 at the age of 21.

The "Wanderjahre" (1743–1752).—This interesting feature, which is often encountered in the lives of many clinicians, lasted from Bordeu's twenty-first to his thirtieth year. In the first four years after his graduation he remained between Pau and Montpellier, acquiring clinical experience through an extensive practice and visits to hospitals, and continuing his anatomical and physiological studies. He next went to Paris where he stayed another four years studying a more extensive clinical material in the hospitals, working in surgery as assistant to L. J. Petit, absorbing with enthusiasm the first elements of the new science of chemistry, with the help of François Rouelle [6], and acquiring the experience of the world—indispensable to the formation of a clinician. He then returned to Pau as demonstrator of Anatomy and superintendent of the mineral waters of Aquitaine. There he remained for two years, continuing his clinical and physiological work and studying the clinical effects of the mineral waters, after which time he went back to Paris. His return was preceded by the publication of his masterpiece "On the Position of the Glands and Their Function".

The Paris period (1752–1776) was the last phase of his life, extending from the time of his finally settling in the capital of France at the age of 30 until his death at the age of 56.

Thus, Paris was the great theatre of action of Bordeu, but, although in the Paris environment, he remained a Montpellier physician, for, as with so many great men, his work was really accomplished before 30 and the rest of his life was a simple elaboration of the intuitions of his youth on the shores of the Mediterranean. In fact, his essential role was to bring to the Faculty of Paris, stagnating in a scholastic pseudogalenism, the vivifying Hippocratic spirit of Montpellier. Later, other Montpellier physicians, like Pinel, did the same and helped to make the great clinical school of Paris which we all admire to-day.

In the French capital Bordeu rapidly acquired the position of one of the few leading physicians, but not without struggle as he met with a bitter and passionate opposition.

He became the physician to the rich and powerful, including the King's favourite, DuBarry, and, although not appointed as physician to the King—Louis XV did not fill this post after the death of Senac—he was called in consultation during the King's last illness. In the midst of this extensive practice, together with his work at the Charité Hospital, Bordeu continued his researches and writings, but all his publications were now merely an elaboration of the material collected in his early days in the South. Practice and research were done within the frame of an intense social life, in the brilliant Paris of that period. Bordeu was a friend of the encyclopædists, of Diderot, of d'Alembert, he frequented the salons of the Duke of Chartres, of Madame Montesson, and he was intimate with the famous Mademoiselle de Lespinasse. He loved the Comédie Française and was often seen backstage at the Opera. He remained a bachelor, living with Louise d'Estrées, but this did not hinder him from indulging in numerous amorous intrigues, quite in accordance with the custom of the period. He burned, alas, the candle at both ends, and exhaustion caused his early end: he died of apoplexy—as had been predicted to him by his teacher, Fizes, many years before.

The personality of Théophile de Bordeu was that of a high-class clinician and we can reconstruct it through his published works, and, principally, through the testimonies of his contemporaries. He showed that combination of scientific and artistic qualities which characterizes the Mediterranean clinician. He had the keenness of observation and the clarity of reasoning bound up with the luminosity of the southern landscape and the sharp lines of its horizon. He possessed to a high degree Intuition, that faculty more artistic than scientific, which in Medicine consists in seeing the patient from the inside, in assessing rapidly his total personality, physical and mental, and thus in understanding the whole problem, because patients are not Hearts or Stomachs but are human problems. As every human problem, even though we may be presented with only one aspect of it, involves the whole man and his environment, Intuition becomes the great clinical faculty, allowing for a more efficient human action such as cannot result from a simple addition of signs and laboratory tests. Above all, Théophile de Bordeu possessed that universality and tendency towards comprehensive and general ideas that has always been the essential feature of Mediterranean thinkers.

For the understanding of thinkers like Bordeu we must distinguish the Mediterranean from the Nordic spirit. The Mediterraneans, happy in their beautiful climate and men of few material needs, were stimulated through their leisure towards the accurate observation of Nature, towards precise, although abstract thinking for the conquest of the spiritual world. The Nordics, struggling in their hard climate, have been directed towards defence against adverse natural conditions, and thus towards the conquest of the material world. Religion and Philosophy came from the Mediterranean: machinism is a Nordic product. Mediterranean Medicine is a medicine of great intellectual synthesis and of intuitive understanding. Nordic Medicine is a medicine of experimentation, of mechanical application and of analytical reasoning. The typical Nordic physician is a man of deep specialized knowledge and master of technique. The typical Mediterranean physician is an inspired clinician, a man of broad vision, of wide culture and of varied activities.

Medicine in general needs these two approaches, but we have the tendency to follow the Nordic more than the Mediterranean approach. This has been a mistake, and for that reason some contact with Mediterranean intellects like that of Bordeu becomes necessary. The slick ingenuity of a single track mind makes for great and spectacular technical developments but the rich and fruitful intuitions of a universal mind will always prove of greater service to humanity.

The Doctrine of Internal Secretions

The essential work of Bordeu has been the development of the principles of Constitutional Medicine, as introduced by Hippocrates. These principles are : (*a*) Principle of Integration in health and disease ; the organism is a whole, and acts as a whole ; disease is a total, "psychosomatic" reaction. (*b*) Principle of Ætiological constellation. Disease represents the reaction of our φύσις, our constitution to adverse environmental factors, and thus, it is determined by a combination of various environmental factors and individual constitutional features. (*c*) Principle of Natural healing powers. Cure is based on the natural, self-regulating power of the organism, on its endeavour to restore its balance disturbed by the adverse environmental factors.

It is by thinking and developing the first of these principles, that of integration, that Bordeu discovered the function of internal secretion. Before Bordeu physicians were divided in their ideas about the mechanism of integration of the organism. Many accepted the conception of Alkmeon (sixth century B.C.), according to which the organism was a whole and acted as a whole, because all its parts were integrated by the brain. Others accepted the Hippocratic conception of humoral (or chemical) integration, according to which it was the humours of the body that effected the correlation of all parts and thus allowed the organism to act—and to react—as a whole. Bordeu accepted that both these mechanisms existed normally, and the conception of this double mechanism of integration (nervous and chemical) remained in our science until a few years ago, since when physiological researches, such as those of Sir Henry Dale, allowed us to unite these two mechanisms into the conception of neurohumoralism.

In thinking of the mechanism of nervous integration Bordeu hit on the doctrine of cerebral localization.

" We are led to believe that every organ has an impulse coming from the brain, which itself is so constituted that its different parts have different functions and control the corresponding nerves, so that what takes place in the organs is but the effect and image of what first occurs in the brain. In a word, we believe that functions first begin in the brain, which is divided into as many compartments as there are organs, and it is so constructed that it stimulates this or that organ, and regulates this or that function through what occurs at the origin of the nerves of the organ; this may be but a more or less pronounced action of a certain part of the blood vessels." (*Œuvres complètes*, tome 1, pp. 201-202).

In his elaboration of the Hippocratic humoral mechanism of integration he is led to the conception of internal secretions. How is it that the humours correlate all parts of the body into a harmonious whole ? The answer is found in following passages of Bordeu's works.

" Each of the organs serves as a factory and laboratory of a specific humor which it returns to the blood after having prepared it within itself and imparted to it its own intrinsic character . . . . The blood has peculiar qualities which it has acquired in the tissues from where it comes. Every organ sends to it continuous emanations and thus the blood carries in its torrent extracts of all organs, which are indispensable for the life of the whole (*Œuvres complètes*, II, p. 942). The blood bears within itself extracts of all the organic parts, each of which is necessary to the well-being of the whole, and possesses specific qualities and properties beyond the reach of the chemist's experiments " (*Œuvres complètes*, II, p. 943).

Thus, Bordeu, developing the Hippocratic ideas, introduced into scientific thought the conception of internal secretion as of a general function, a function of all organs, all tissues, all cells. This conception was elaborated with great precision by Brown-Séquard and d'Arsonval (1891), but with the intense study of the specialized organs of internal secretion it was nearly set aside. We are returning to it. We know that all cells possess, to a more or less high degree, incretory function, and that the glands of internal secretion are simply an accumulation of cells possessing this function to a high and specialized degree. This is the basic principle of Endocrinology.

The Special Organs of Internal Secretion

The relation between the omnicellular incretory function and the special endocrine glands was not well understood in those days (and has, in fact, been only recently understood), but parallel with the work that gave us the omnicellular incretory function was proceeding work on special endocrine glands, and in this work, also, Bordeu played an important part.

The first organ studied as an endocrine gland was the testis. The experiments on human castration, and the differences of various features amongst the sexes, helped the ancient Greeks to accept that the "semen" played a great role in the development of masculine features and qualities, and this idea was embodied in the words of Aretaios, "The semen makes man".

Thomas Willis developed more fully this conception in his *de Cerebri Anatome* (1664), where he wrote that the blood receives from the genitals "certain particles imbued with a seminal tincture, which, carried back into the bloody mass makes it vigorous and inspires to it a new and lively virtue".

Bordeu goes one step further in this conception of internal secretion of the testis.

" The semen imparts a firm and masculine tone to all parts as soon as it can be drawn off and sent into the humours and solids by its natural organs. It sets a new seal upon the animalism of the individual, who is, in part, subject to the action of this creative liquor " (*l.c.* p. 842). . . . This liquor (semen) penetrates the mass of the humours. . . . It has the property of consolidating the parts and of nourishing them. It excites and stimulates all the fibres. It is the cause of that fetid odour exhaled from vigorous males. . . . In a word, it must be considered as a special stimulus of the machine which physicians have not sufficiently considered.

Apart from the general concepuon of the masculinizing action of the testicular internal secretion, let us note the detail of the determination by this secretion of the "fetid odour" of vigorous males. Testosterone stimulates the sebaceous glands, and of course the odour of the sebum secretions was more pronounced in the eighteenth century which was not distinguished by cleanliness.

Bordeu accepts what we call, to-day, the psychosomatic link through the endocrines—a notion developed in our day by our former president, Sir Walter Langdon-Brown. "The aura seminalis serves more than the other liquors as a link, or intermediary, between the body and the mind (*Œuvres complètes*, p. 959).

Next to the endocrine function of the testis, Bordeu points to the endocrine function of the ovary, and this, possibly, for the first time in medical thought, although the first description of the effects of experimental female castration was by Aristoteles. In describing these effects of female castration in fowls Bordeu adds, "These phenomena prove that females may like males, receive from the generative organs a vital impulse which stimulates and influences them. This is certainly true of women" (*Œuvres complètes*, p. 950).

From a nosological, or clinical, scientific point of view, Bordeu describes—this, also, I think, for the first time—the existence of a female eunuchoidism parallel to the well-known male eunuchism and eunuchoidism (*Œuvres complètes*, p. 950).

Further Work on Constitutional Medicine

Théophile de Bordeu elaborated the second Hippocratic principle, that of the Ætiological constellation. In the consideration of the external ætiological conditions he stressed the importance of the psychological and social factors, developing, thus, the "psychosomatic

principle". "Look for all factors", he writes in his *Maladies Chroniques*, "which bring the disturbance in the patient, particularly in chronic cases. Look, particularly, for the mental factors, frequently more potent, more difficult to ascertain, more important to consider." He also stressed the internal, constitutional, ætiological factor in disease.

We read in his *Recherches sur les maladies chroniques*:

" The physician must apply himself to know the temperaments that are the sources of many diseases. He must not devote himself entirely to the study of epidemics and diseases of certain countries while neglecting the study of the living body. It is less important to know which constitutions in the air determine the epidemics, than to know which temperaments can be affected. There are temperaments that fecundate easily the germs of the diseases. There are others that convert all diseases in those that are proper to them. This is demonstrated by the asthmatics or gouty, who show asthma or gout although pleurisy or angina reign in that epidemic."

There was a time when the ideas embodied in this passage were forgotten, but they have come into the foreground again, and the lines of Bordeu can be inserted in the most modern book of Pathology. And how about this . . .

"Why does the virus of smallpox not attack those who have already had this disease, although in the course of epidemics it penetrates into the blood mixed with the air that is breathed, the saliva, the foods . . . whereas, when inoculated in those who have not had smallpox it gives the disease. One must think that if this virus does not act, it is that it does not find in the body the favourable disposition, because this favourable disposition has been destroyed with the first attack of the disease. . . ." (*Recherches sur les maladies chroniques*. Edition Roussel, p. 89, xxxiii.)

In developing the third Hippocratic principle, that of the Natural Healing power which demands that the physician use methods which help the constitution in its fight against disease, Bordeu showed the importance of mineral waters in treatment. He thus became, with his father, a pioneer in Hydrology as well as in Endocrinology. His observations on the course of the disease in patients submitted to medical water cure at Bareges can be read with profit by modern hydrologists, particularly in days when we have a tendency to neglect that most valuable therapeutic method. He noted in some cases, particularly of rheumatism, an initial aggravation in the course of an hydromineral cure, and compared this aggravation to the "crisis" in acute diseases, and showed that like the crisis it heralded an improvement in the condition of the patient.

As a real Hippocratist he poured scorn and mockery on those who believe they can scarcely prescribe enough drugs nor order sufficient venesection, and who thus obstruct the Natural resistance. "It seems to me I hear Nature crying, 'Do not hurry, let me alone. The drugs that you cram into the body of the sick will not cure, it is I, alone, who cures. The moments in which you appear the most agitated are those in which I save myself most—if you have not taken away my forces. It would be better if you trust in me, abandoning all your doubtful remedies'."

I shall only touch the question of his elaboration of Hippocratic "physis" into the Montpellier "vitalism". Bordeu's work on this point seems to be highly speculative, but it has been the inspiration of the more precise work of Bichat.

Théophile de Bordeu did not limit himself to studying general pathology but made some important researches on special clinical problems, particularly on the pulse, and published an important work on this subject based on his observations in the Charité Hospital.

Discussion

Medicine is part of History, and History is continuity. The stream of scientific thought is continuous, and although in this continuous flowing we can note—often artificially—certain landmarks, we cannot speak of originators. We cannot cut into time. Nothing begins in the History of Science and when someone expresses an idea it is already in the air. Bordeu represents a landmark in the History of Endocrinology, in the same manner as Berchtold, Claude Bernard, Addison, Brown-Séquard, represent other landmarks, but we cannot call any one of them the father of Endocrinology. Questions of priority, naïve satisfactions of individual, national and racial prejudices go against the sense of History, which is the sense of continuity.

Even from that point of view, the role of Bordeu in Endocrinology has been discussed because, as Garrison [7] writes, "He was very close upon the modern theory of internal secretion and hormonic equilibrium, but as he made no experiments his ideas can be regarded as sheer theory only". But "Theory", which in the original Greek means the highest form of thinking, is the basis of scientific development. Science is not a mass of more or less connected technologies, but is a product of human thought. Observation and experiment are instruments of human thought, and are useless when divorced from thinking. We have forgotten that in our supermechanized days, and thus risk to merit the reproach of Nietsche

to his contemporary professors, who, "work hard day and night so that they may not have time to think". On this principle we should dismiss the ideas of Newton or Einstein as "pure theory". Curiously enough, those who consider Bordeu as a pure theorizer extol Brown-Séquard, who, at the famous meeting of the Société de Biologie of Paris on June 1, 1889 (one of the many birthdays described for endocrinology), largely said what Bordeu had said—but "he made an experiment". However, the experiment of Brown-Séquard was false. The saline extract of the testicle prepared with a rough technique could not contain any testicular hormone, and the result of its injection were simply due to autosuggestion. . . . No experiment, but right thinking with Bordeu, wrong experiment, but right thinking with Brown-Séquard.

All this shows that, although clinical observation and experiment are indispensable for the development of Science, the thinking, the theorizing which is behind and above observation and experiment, is much more important. It is a question of thinking right or wrong, and to think right we must follow the reasoning of the great intellects of the past. History of Medicine is important in Scientific Method.

Behaviour of the Uterus in Early Pregnancy

By A. C. PALMER, F.R.C.S., F.R.C.O.G.

Consulting Obstetrician and Gynæcologist, King's College Hospital. Senior Surgeon Samaritan Hospital, London

MY task is to describe and demonstrate one physical sign of early pregnancy, and at the same time draw attention to some of its implications. I will begin by a brief account of its nature.

The sign consists of an inherent muscular rhythm which—as I believe—comes into being as soon as the ovum is embedded and can be recognized clinically when the first period is due to be missed. Between the *4th and the 8th week* the rhythm becomes obvious and should not be missed by those accustomed to look for it. By the *10th week* the rhythm is changing and is a little more difficult to recognize, but it should not be missed provided the time factor is attended to. Between the *12th and 16th week* the time factor dominates the position, attendance to it becomes tedious but if it is neglected, the movement will not be recognized. By the *20th week* the cycle has become so long that its recognition as a rhythm is a matter of chance.

In brief, the action to be described and shown is an inherent muscular rhythmic cycle, easy to recognize and demonstrate up to the *10th week*, but progressively more difficult to appreciate as time goes on.

No remarks about early pregnancy would be complete without some mention of Hegar's sign, namely, that about the *8th week* the abdominal and vaginal fingers give the impression of coming into contact with each other through the walls of the decidual space.

I have found Hegar's sign disappointing and elusive, and it may be that the rhythm which I shall describe explains the inconstancy of Hegar's sign. In 1938, after one of those repeated failures to demonstrate it to a group of students, I was palpating the body of a seven weeks' pregnancy, when the uterus disappeared from between my fingers; I thought I had pushed the body to one side but could find it nowhere else in the pelvis. After a while the body reappeared in its proper position, precisely where it was before it disappeared. This confusing experience led to the search for a similar happening whenever the opportunity occurred and it was often found that the body disappeared, as it had done on the first occasion, provided one waited for what then seemed a long time.

It was evident that a movement of some sort was taking place and the idea took shape that one might learn something by using a watch to time the period of absence. In the course of time, always using a watch, it was discovered that a rhythmic movement was taking place; that a period of relaxation, lasting about 30 seconds was followed by a period of increased

tone, lasting another 30 seconds; the whole cycle taking a minute for completion before it was repeated. With increasing experience, we found that a rhythmic muscular cycle continued regularly without interruption and without noticeable change, from the *4th to the 8th week*, that is to say, during the interval between the first and second missed periods.

The beginning of this idea was stumbled upon in 1938, as a result of failure to demonstrate Hegar's sign, and the conclusion, which has taken a few minutes to describe, was reached in 1945, after seven years of trial. At that time, it was thought to be probably true. Since then, so many registrars, housemen, and students have recognized the rhythm that the probability of truth has passed into practical certainty. The rhythm has been observed in *440* cases examined during the *first twelve weeks*; *200* of these have been before the *eighth week*.

Service women, posted to gun sites, often missed one or two periods and occasionally three; almost without exception, the uterus was the typical virginal one, semi-cartilaginous in consistency and able to be flicked to and fro in the pelvis, rather like a boomerang. In the few exceptional cases which were pregnant, the uterine rhythm was obvious.

A short film was shown to demonstrate that the uterus in early pregnancy is possessed of an inherent rhythm of contraction and relaxation, the intervals of which are dependent upon the duration of the pregnancy.

The film opened with a sequence of five graphs showing the relative rhythms of contraction and relaxation occurring at 4 - 8 weeks, 10 weeks, 12 weeks, 16 weeks and 20 weeks (Figs. 1, 2, 3, 4, 5). There followed a demonstration of this movement on an excised uterus

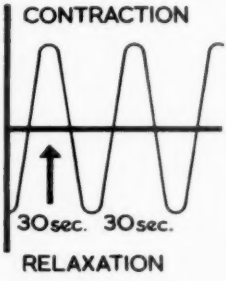

FIG. 1.

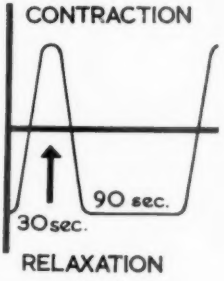

FIG. 2.

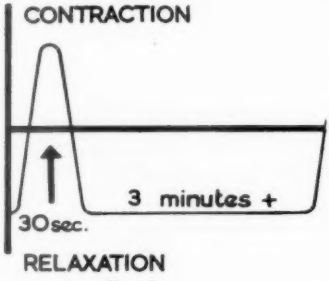

FIG. 3.

FIG. 1.—4–8 weeks. The regular cycle between the fourth and eighth week. The tonic phase of 30 seconds, followed by a relaxation phase of 30 seconds, and regularly repeated.

FIG. 2.—10 weeks. The relaxation phase now lengthened to 90 seconds, while the tonic phase is unchanged.

FIG. 3.—12 weeks. The time of relaxation is doubled, while the tonic phase is practically unchanged.

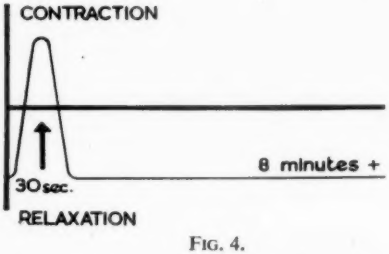

FIG. 4.

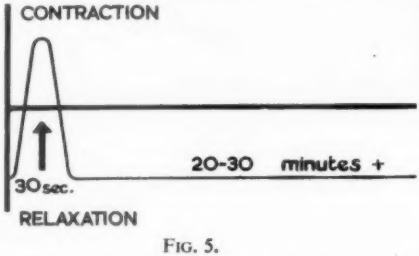

FIG. 5.

FIG. 4.—16 weeks. The time of relaxation is further lengthened to a minimum of 8 minutes, while the tonic phase remains about the same as at 8 weeks.

FIG. 5.—20 weeks. The relaxation period varies up to 30 minutes, while the tonic phase is practically unchanged.

behaving outside the body, as a uterus 6 weeks pregnant behaves inside the body. The resemblance had been brought about by artificial means.

The graphs were followed by a picture of the uterus at the height of its tonic phase. At this period, its consistency is that of a new tennis ball (Fig. 6), the fingers come in to palpate the body and it is shown to be resisting (Fig. 7); eventually it softens and the fingers sink into the body (Fig. 8). The uterus then disappears for a short time (Fig. 9), perhaps 5 or 10

FIG. 6.

FIG. 7.

FIG. 6.—The approximate size and shape of a uterus 6 weeks pregnant, at the acme of the tonic phase.

FIG. 7.—The fingers gently palpating the uterus shown in Fig. 6, its consistency being that of a new tennis ball.

FIG. 8.

FIG. 9.

FIG. 8.—The fingers sinking into the softening uterus, as relaxation begins.

FIG. 9.—The uterus, having reached the nadir of relaxation, has become impalpable for a short period, before it reappears, as in Fig. 8.

seconds, when it reappears and gradually regains its tone, pushing out the fingers as it passes towards the acme of the tonic phase. This part of the picture is intended to indicate the normal action in its proper time. The first repeat emphasizes the change and shortens the time; the second repeat is an attempt to emphasize the change still further, the time is again shortened but the uterus does not disappear.

(1) *What is the Purpose of This Movement?*

I think it is true that the placenta is not fully formed until round about the *12th week*, when in conjunction with the fœtal heart it becomes mainly responsible for the fœtal circulation. Up to this date there is no special mechanism for supplying nutriment to the ovum, unless this purpose is served by the rhythm of the uterus which regularly empties and refills a few large blood lacunæ in the walls of the uterus. After the fœtal heart and the placenta with its numerous blood sinuses have taken over the fœtal circulation, it is no longer necessary for the placental sinuses to be emptied and refilled so frequently, and therefore the rhythm changes and the resting phase becomes steadily longer as the pregnancy proceeds.

(2) *Is the Knowledge of This Uterine Cycle of Any Clinical Use?*

Those of us who are familiar with this movement regard it as being for practical purposes a certain method of diagnosing pregnancy between the *4th and the 8th week*; after the first but before the second missed period, in a woman who has not been seen before, provided she will relax her abdominal muscles and the body of the uterus will nestle comfortably between the fingers. It is desirable to have the bladder empty, and the rectum not too full. When the pelvis contains a large cervical fibroid or an ovarian cyst, it may be impossible to feel the uterus.

(3) *Is the Cycle Easy to Recognize?*

With an instructor standing by, half a dozen students in succession will assert that they have felt the change. To recognize the movement under instruction is one thing; to feel it without guidance is a different matter, for the fingers have to find out what they are expected to feel and this requires some practice. To those not familiar with the sign, I would say that without the use of a watch, allowing 30 seconds for each half of the cycle, there will be a long period of disappointment, because *5 seconds* without a watch, seem like *5 minutes*. On the other hand, with the body of the uterus comfortably resting between the fingers, and the time noted by a watch, there will be some initial failures but those who persevere will succeed.

Perhaps the most striking feature is that of a tense elastic body fading away and disappearing from between the fingers.

It matters little whether the patient is in the dorsal position or the Sims' position. With the patient on her back and the legs in the sole to sole position, it is easy to bring the tactile eminence of the vaginal finger into contact with the under-surface of the body; whereas, with the patient on her side, the tip or side of the tip of the vaginal finger must be used. In our experience one method is as good as the other. Some women relax the abdominal muscles better when on the left side, others when on the back. Every now and then it is useful to try both positions.

The cycle as described is the standard conduct between the *4th and 8th week*, but some slight variation in time should be allowed to uterine individuality.

The effect of anæsthesia.—A few cases have been examined at six weeks. It was found that the cycle continues under anæsthetic but the resting phase is prolonged from 30 seconds to a minute and a half or more.

Threatened miscarriage.—The rhythm continues unchanged as it does in incomplete abortion.

Carneous mole and ectopic.—I do not know what happens in a carneous mole [1] but would expect the rhythm to have ceased after the death of the ovum; nor do I know what happens in ectopics; the rhythm might or might not be present, but the additional pelvic lumps and traumatic inflammation, are likely to make palpation of the uterus difficult.

No suggestion is made that the recognition of painless contraction and relaxation in the pregnant uterus is anything new. It can be felt by abdominal examination at the *20th week*, if sufficient time is allowed.

Braxton Hicks was writing on this subject in 1872. He was then suggesting that the changes in uterine tone were spontaneous and not due to outside stimulus. He is reported (*see* Thoms, 1935) to have stated that the alterations in uterine tone could be observed after the *4th month*. Reference to his original article (1872) shows that he mentions the *3rd month*. He says: "After many years' constant observation, I have ascertained it to be a fact that the uterus possesses the power and habit of spontaneously contracting and relaxing from a very early period of pregnancy, as early, indeed, as it is possible to recognize the difference of consistence—that is, from about the third month.

"Up to the end of the second month the walls are still dense, but after this time the fundus will begin to be elastic, and variation in its consistence is recognizable as the end of the third month is approached."

[1] Since this paper was written, Mr. Harford Rees has told me that the rhythm fades away and disappears in carneous mole.

It is, I think, stated in the latest edition of Eden and Holland (1948) that the movement cannot be felt much before the *16th week*.

Herman stated in 1913, that Braxton Hicks was the first to point out that contractions are regular and rhythmical during pregnancy. Those before him had observed them as the result of stimulating the uterus.

Herman says: "They can be felt as soon as the uterus is big enough for the difference in consistence to be felt by the abdominal hand. To feel them, lay the hand on the uterus without friction or more pressure than that necessary for full contact with the uterine body. If relaxed at first, the uterus will be felt to become firm; if at first it is firm, it will be felt to become flaccid. Keep the hand on the uterus from 5–20 minutes. The interval between the contractions, is seldom as long as 20 minutes, they generally occur every 5–10 minutes. As the contractions pass off the uterus may become so soft that its outline can scarcely be made out at all and in a hasty examination, the presence of a pregnant uterus may not be noticed."

Professor Munro Kerr (1939) mentions occasional contractions or hardening of the uterine walls, appreciated by the educated touch from the 12th week.

It is, however, a fact, that a rhythm exists and can be recognized as soon as the first period is missed.

Observations on the Origin of the Lower Uterine Segment in Pregnancy

By Professor F. J. BROWNE

THERE are three main views on the origin of the lower uterine segment in pregnancy:

(1) That it is the isthmus of the uterus that has been expanded or opened up, and taken up between the second and third months of pregnancy, to form part of the ovum chamber.

The isthmus, first described by the anatomist Aschoff of Freiburg, 1906, is that part of the cervix lying between the anatomical internal os above and the histological internal os below. Its average length is 4·5 mm. (Stieve), that is, about a quarter of an inch. Though forming part of the cervix its endometrium resembles that of the corpus in that the glands are simple tubular. It differs from the corpus, however, in that its endometrium does not respond well to the action of the sex hormones; it is not shed to any great extent at menstruation and the glands contain little or no glycogen (Frankl). There is little or no decidua formed in pregnancy. The glands of the isthmus also differ from those of the cervix in that they contain no mucus. Stieve has shown that after the second month the isthmus is opened up and expanded so as to become part of the corpus. This coincides with the time when the ovum completely fills the ovum chamber. When it is completed the histological internal os has become the internal os of the uterus and remains so till term. The anatomical internal os according to this view now lies at the level of the retraction ring of Barbour, that is at the junction of the upper and lower uterine segments.

This view of the origin of the lower segment has received almost universal support. Thus it is accepted by Stieve (1927), Stander, Oscar Frankl and by Munro Kerr and Chassar Moir. Barbour (1907-8) called it an "ingenious hypothesis" but did not accept it.

That the isthmus of Aschoff forms at least part of the lower segment, I have been convinced by the following observation. On 14.9.49 I did an abdominal hysterotomy for therapeutic reasons on a patient 71 days (10 weeks, 1 day) after the first day of the last menstrual period. The periods had previously been regular, type 3–4/24. A lower segment operation was done and a transverse incision through the muscle was made about half-inch below the upper level of firm attachment of peritoneum. On inserting the forefinger, which would in a uterus at term have been in the cavity of the uterus, I found that my finger was below the internal os. The internal os was partly dilated and easily admitted the forefinger which was passed

up to the fundus. The ovum was found in the left cornu and was removed. The decidua capsularis had not yet fused with decidua parietalis (Fig. 1).

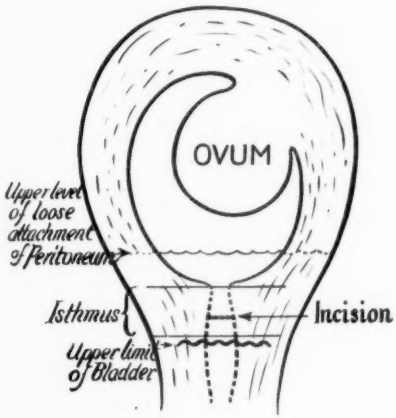

FIG. 1.

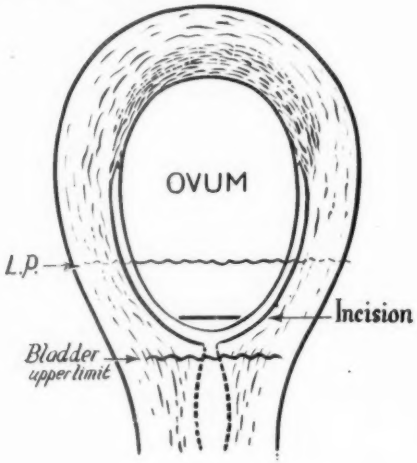

FIG. 2.

This suggests that the lower uterine segment is at least partly formed from the isthmus and that it had not yet (at 71 days) been opened up and taken up into the corpus. That the process had begun, however, is suggested by the finding that the internal os was partly dilated.

Another observation was made on 9.11.49. Abdominal hysterotomy (lower segment operation) was done at 78 days (11 weeks, 1 day) after first day of last menstrual period. The incision into the uterus was made 1 inch below the line of firm attachment of peritoneum. The finger entered the cavity of the uterus as in a lower segment cæsarean section at term. The ovum now filled the uterine cavity entirely, down to the internal os (Fig. 2).

This suggests that between the 71st and the 78th day the ovum had grown sufficiently to fill the uterine cavity and that to supply extra accommodation for it the isthmus had been opened out so as to form part of the ovum chamber.

(2) The second view is that the lower segment is formed from the lower part of the corpus only, the cervix not contributing any part of it. This view was held by Barbour and Von Franqué, who therefore believed that there was a lower segment, not only in the pregnant but also in the non-pregnant uterus. Its upper limit was the firm attachment of peritoneum on the front of the uterus which v. Franqué pointed out was 9 to 12 mm. above the internal os. Because of the observation recorded above I do not think that this view is correct.

(3) The third possible view is that the lower segment is formed both from the isthmus and from the lower part of the corpus, the part, that is, corresponding to the area of loose attachment of peritoneum. Here let me call attention to one or two anatomical points. The relation of the bladder to the supravaginal cervix is very variable, but, so far as I have been able to observe, it never reaches higher than the histological internal os. It, therefore, does not cover the isthmus. This is, of course, what we would expect if the isthmus is to form part of the lower uterine segment which has to expand passively during labour. The peritoneum is, therefore, reflected off the upper surface of the bladder at the level of the histological internal os or even below that level. As it passes up over the front of the uterus it is separated from the muscle by a layer of loose connective tissue which extends upwards above the anatomical internal os for about a half-inch. The peritoneum, therefore, covering the isthmus and this lower half-inch of the corpus is loosely attached.

I believe this third view to be the correct one for the following reasons:

(*a*) I cannot believe that the isthmus which in the non-pregnant uterus measures 4·5 mm. could ever expand sufficiently to form the entire lower segment which at term reaches to 4 in. (100 mm.) above the internal os. To do so it would have to expand about 16 times, whereas the whole uterus only enlarges to about 4 to 6 times its original size.

(*b*) If the lower part of the corpus does not form part of the lower segment there would not seem to be any purpose in its being covered by loose peritoneum. Wherever in the pelvis an organ is covered by loose peritoneum, that is wherever the peritoneum is separated from the muscle by loose connective tissue, the purpose seems to be to allow for the rapid distension of that organ, e.g. the bladder and the rectum.

(*c*) Constriction rings form in the uterus chiefly in the lower segment, above the internal os. They do not form at the level of the retraction ring of Barbour as they might be expected to do if the anatomical internal os, at which a constriction ring would be most likely to form, were at the level of the retraction ring, as it would be if the lower segment had been formed entirely from the isthmus. If, however, the lower segment comes from both the isthmus and the lower half-inch of corpus the anatomical internal os would lie somewhere about the middle of the lower segment.

SUMMARY

Evidence is brought forward to show that the lower uterine segment in pregnancy is formed partly from the isthmus of the uterus, partly from the lower half-inch of the corpus, that is the part corresponding to the area of loose attachment of peritoneum.

VON FRANQUÉ, O. (1897) Cervix u. Unteres Uterinsegment. Stuttgart.

Professor W. C. W. Nixon described a case which might support Professor Browne's ideas on the lower uterine segment. Recently he terminated a pregnancy of 24 weeks by vaginal hysterotomy using von Friesen's technique. Above the internal os a ring was felt which made extraction difficult since it interfered with the manœuvre of internal version. It was possible that the ring marked the junction of the lower and upper segment.

The Rarer Causes of Abdominal Pain in Pregnancy

By GORDON LENNON, Ch.M., M.R.C.O.G.

Nuffield Department of Obstetrics and Gynæcology, University of Oxford

MY interest in this subject was stimulated by a case of acute salpingitis occurring at the 4th month of pregnancy. Now, on page 458 (6th Edition) of "Ante-natal and Post-natal Care" (Browne, 1946), it is stated that salpingitis does not occur during pregnancy. These are the facts of the case:

Case history.—Mrs. G. P., aged 32, para 4, was admitted to the Radcliffe Infirmary on August 14, 1948, complaining of severe abdominal pain of three hours' duration. When out shopping she had suddenly developed sharp pain in the right side. The pain had spread out over the lower abdomen about one hour after its onset and was aggravated by movement. The patient had felt sick but had not vomited. Menstruation had been regular till April 14, 1948, since when there had been amenorrhœa. The only other significant point in the history was that, at the age of 20, there had been a history of "inflammation of the left ovary".

The woman was obese, looked distressed and in pain. Temperature was 98·8° F. and pulse-rate 108. There was marked tenderness and rigidity over the lower abdomen, particularly in the right iliac fossa. The enlarged uterus was palpated with difficulty and thought to correspond in size to the duration of amenorrhœa. There was no "shoulder-tip" pain. Vaginal examination revealed a closed cervix with no evidence of bleeding. Tenderness was elicited in the right lateral and posterior fornices. The urine showed no abnormal constituent. A diagnosis of acute appendicitis complicating pregnancy was made and immediate operation decided upon.

At operation frank pus was found free in the peritoneal cavity. The uterus was enlarged to the size of a sixteen weeks' pregnancy. The appendix was normal. No Meckel's diverticulum was found. The left tube showed old-standing hydrosalpinx and was buried with the ovary in the broad ligament. The right tube was deeply congested and pus dripped from its fimbrial end. This pus gave a pure growth of *B. coli*. Sulphamezathine and penicillin were started post-operatively. Ten hours later the patient aborted, the products of conception being passed intact. Convalescence was entirely satisfactory.

Discussion

Cases have been recorded by Fruhinsholz, Hamant and Mosinger (1929), Devraigne and Ravina (1937), Bidoire (1939), Brindeau (1939), and Metzger (1939). Their cases occurred about the second month of pregnancy, sometimes earlier, and were almost invariably diagnosed as ectopic pregnancy or acute appendicitis. Many had, in addition, chronic salpingo-oophoritis, and *B. coli* and staphylococci were obtained. Bidoire mentions that there was no great rise of temperature in his case. DeLee (1938) states, "Sometimes a pus tube forms after conception has occurred, the woman having been infected and impregnated at the same time." I have been unable to find a record of any case where gonococci were found on culture.

To ascertain if there was also intra-uterine infection I had sections made of the membranes of the ovum passed. This clearly shows focal infiltration by inflammatory cells (Fig. 1).

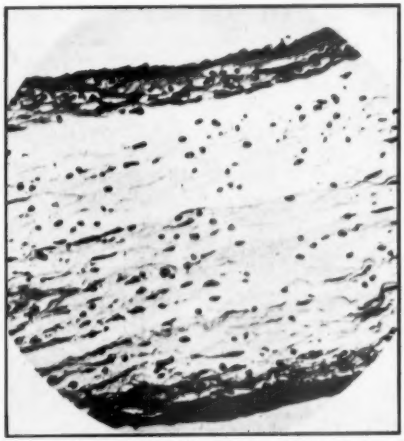

Fig. 1.—Inflammation of fœtal membranes from case of abortion with acute salpingitis. (High power.)

A similar piece of membrane was examined from another case of abortion of comparable duration but where there was no co-existing salpingitis. The absence of inflammatory cells is evident in Fig. 2. Dr. A. H. T. Robb-Smith (Department of Pathology) assures me that

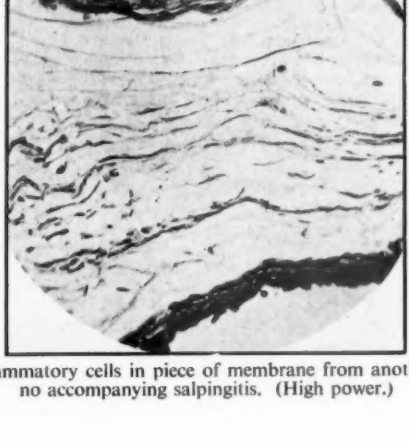

Fig. 2.—Absence of inflammatory cells in piece of membrane from another case of abortion with no accompanying salpingitis. (High power.)

it is not uncommon to find evidence of inflammation of the membranes, particularly in cases where the fœtus is macerated. In this case the fœtus was quite fresh. A pathologist will be more likely to see cases of incomplete abortion where infection is present than cases of abortion where the ovum has been expelled intact.

It is only possible to speculate as to the route of infection. Was there flare-up, due to the pregnancy, of an old focus? In favour of this was the presence of adnexal disease on the left side. The history of left "ovarian inflammation" at the age of 20 indicated some pathological condition before two of the pregnancies; why, then, had infection not flared up during the succeeding pregnancies and before this pregnancy? At the fourth month of pregnancy any space in the uterus between membranes and uterine wall must be merely potential and likely to exclude direct spread from outside. Yet the membranes showed inflammatory cells. Was this spread from the salpingitis? The possibility of criminal intervention was entertained but was denied. There remain the channels of lymph or blood vascular spread.

Mild salpingitis may account for some cases of pain in the early weeks of pregnancy for which no adequate explanation is ever forthcoming. This would suggest that the condition is commoner than is supposed. But any pre-existing salpingitis must not be of such a degree as to prevent the passage of the fertilized ovum into the uterus.

This woman could not have been expected to make the good recovery she did had her illness occurred in the years before chemotherapy. I saw her again a fortnight ago and she was 5 months pregnant, a tribute to the almost complete resolution in her previously inflamed tube. On this occasion she has had a nagging lower abdominal pain worst at the 3rd month, but never incapacitating.

Browne (1946) and also Blakeley (1933) assert that 80–85% of women complain of definite abdominal pain at some time during pregnancy. Excluding the signs of an intra-abdominal catastrophe, the pain is dismissed as being due to pulling on the round ligaments, previous obstetric trauma, orthopædic strain, &c. It is said that the mortality of acute appendicitis in pregnancy is due to delay. Better to be alive with an abdominal scar than dead without one.

Angular pregnancy as distinct from interstitial pregnancy: I find quite often when examining a patient early in pregnancy that one lateral half of the uterus is thicker, or more evident, than the other (Piskaček's sign). The woman often has quite severe unilateral pain—right-sided—and even threatened miscarriage. Indeed, she may miscarry and then the diagnosis is not in doubt whereas previously there may have been worry about the presence of ectopic pregnancy, twisted cyst or fibroid and pregnancy. I believe this condition of angular nidation to be quite common. Munro Kerr (1949) and Fahmy (1944) have stressed it and drawn attention to the difficulty in such cases of manual removal of the placenta in the third stage of labour. Some degree of angular implantation might well be the determining factor in the Duncan method of delivery of the placenta, as opposed to the Schultze mechanism when the placenta is in the fundus. It would be a question of degree of angular implantation as to whether the placenta slides out or whether part gets nipped in a cornual contraction ring—the latter state being quite a common finding at manual removal in Flying Squad cases (Joyce and Lennon, 1948).

Does stretching of scar tissue cause abdominal pain? Recently I had a woman at the 33rd week of her first pregnancy, who complained of sudden severe abdominal pain localized to the umbilicus and around it. This case was further complicated by the fact that her retroverted uterus had been perforated by a uterine sound a few years before during dilatation for dysmenorrhœa. She stated that the pain felt as though something was tearing. There was no toxæmia and no suggestion of accidental hæmorrhage. The severity of the pain and the marked tenderness caused me to perform laparotomy. The exploration was entirely negative. But the pain was better next morning, despite the abdominal incision. If coughing can precipitate hæmatoma of the rectus abdominis muscle, and even fracture of a rib during pregnancy, is it too much to suppose that the fibrous tissue of the umbilicus may be torn by effort in the later months when it is already stretched?

Lastly, I would consider constipation as a cause of *severe* abdominal pain in pregnancy. A few weeks ago I saw a woman about 5 months pregnant who complained of severe, colicky lower abdominal pain. There was a history of constipation, and certainly there were "rocks" in the colon. Temperature was 101°F. The urine was clear. Her pulse rose to 100, and results to enemata were unsatisfactory. I refrained from chemotherapy. Perhaps the fact that her appendix had been removed eighteen years before saved her from laparotomy! Eventually with movement of the bowel the condition cleared up quickly. She has since remained well.

Those who are interested in the wider aspect of abdominal pain in pregnancy will find the greatest help from a perusal of the Honyman Gillespie Lecture of 1944 by E. Chalmers Fahmy, and as a basis for discussion I reproduce the causes as divided by him into three trimesters:

First Trimester	*Second Trimester*	*Third Trimester*
Iliac fossa pain	Hydatidiform mole	Hæmatoma of rectus abdominis
Round ligament pain	Acute hydramnios	Costal margin pain
Previous obstetric trauma	Pyelitis	Concealed accidental hæmorrhage
Ectopic gestation	Ureteral spasm	Rupture of uterus
Retroflexion of gravid uterus	Appendicitis	Rupture of vein on uterine wall
Ovarian hæmorrhage	Fibroid tumour	Torsion of gravid uterus
Angular pregnancy	Ovarian tumour	Epigastric pain
	Adhesions	Gall-bladder pain
	Intestinal pain	Pain of orthopædic origin

Section of Orthopædics

President—NORMAN CAPENER, F.R.C.S.

[*October* 4, 1949]

"Slipped" Lower Femoral Epiphysis in a Case of Eunuchoid Gigantism.—E. T. BAILEY, F.R.C.S.

The patient was a man of 29 who first attended for orthopædic advice in March 1949, complaining of pain and swelling in the right knee which was constantly giving way.

Previous history.—Examined medically at the age of 19, when non-descent of testicles, failure of voice to break and lack of body hair were observed. One year later he joined the Army. Sustained a fall on the ice, 1941, and strained his right knee which subsequently continued to give rise to symptoms. Diagnosed as displaced cartilage and eventually boarded out of the Army with this record and a diagnosis also of hyperplasia of anterior pituitary gland. Since discharge he has undertaken various occupations and has had recurrent pain and swelling of the right knee.

Examination.—Examination showed local tenderness with slight give on pressure over lower right femoral epiphysis. X-ray showed no actual displacement, but well-marked epiphyseal line of all long bones. Testes undescended. Voice unbroken. Comparatively hairless. Mental state adolescent. General poor muscle tone and laxity of ligaments, with hyperextension of joints. No other relevant findings.

X-ray of skull (Fig. 1) showed normal pituitary fossa, but marked hyperpneumatization of sinuses. Long bones showed well-marked persisting epiphyseal lines (Fig. 2), also the vertebræ. Head and tuberosities of humerus united to shaft and epiphyses of metacarpals and phalanges uniting (Fig. 3).

FIG. 1.—Hyperpneumatization of sinuses. Pituitary fossa normal.

FIG. 2.—Persistent epiphyseal line of lower end of femur and upper end of tibia.

FIG. 3.—Epiphyses of phalanges fused. Metacarpal heads commencing to fuse.

Treatment.—Treated by immobilization in gaiter plaster for five weeks, followed by muscle re-education. Symptoms relieved.

General endocrine treatment given, consisting of implantation of 1,000 mg. of testosterone into the abdominal wall in April 1949 with a repeat dose of 400 mg. in September 1949. The effect of the implantation was rapid with breaking of the voice within three weeks, increase in weight and rapid muscular development, hair developed on face, axillæ and pubis. Erections commenced to occur with nocturnal emissions.

Biochemical tests.—(*a*) 22.4.49 (1 week after testosterone implantation): Serum calcium 13·1 mg./100 ml. Serum alkaline phosphatase 15 units.

(*b*) 25.4.49: Urinary calcium excretion—twenty-four hours 2·45 grammes.

(*c*) 20.5.49: Serum calcium 10·5 mg./100 ml. Serum phosphorus 5 mg./100 ml. Serum alkaline phosphatase 10 units.

Was subsequently discharged and commenced work on a farm, but, after a few weeks, while climbing a haystack, fell with injury to knee. No damage to the epiphysis resulted and condition of traumatic synovitis resolved quickly with appropriate treatment.

Mr. J. G. Bonnin: A similar case with less well-marked gigantism is under my care. Attention was first drawn to him in a fracture clinic where he proved to have a classical separation of the lower left radial epiphysis, including a wedge of diaphysis, but only slightly displaced. His age was 39. Enquiry elicited the fact that he had never shaved. His scrotum is empty, he has little pubic hair, and his bones are light and of feminine build. His voice is a little contralto, and he has the pleasant manner of the eunuchoid, completely lacking in aggression. He is quite satisfied with his present condition, and though he was persuaded to try testosterone, has been rather disgusted with the results, and is not anxious to continue. It is thus unlikely that we shall be able to observe the effects of testosterone in hastening the union of the epiphyses.

Tumour of Humerus. (Revised Diagnosis, Case Previously Shown on March 2, 1948. Not published.)—W. D. COLTART, F.R.C.S.

Miss E. D., aged 27.

History.—On 29.8.47 fell and injured her right elbow. X-ray showed a fracture through what appeared to be an osteoclastoma of the lower end of the humerus (Fig. 1A and 1B).

FIG. 1A.

FIG. 1B

FIGS. 1A AND 1B.—X-rays showing fracture through what appears to be an osteoclastoma.

14.9.47: Biopsy of the tumour: Histological report by Professor G. Hadfield and Dr. G. J. Cunningham—"In spite of the presence of a number of osteoclastic giant cells the histological appearances do not conform with those of osteoclastoma, but rather suggest a reticulo-sarcoma as the most likely diagnosis" (Fig. 2).

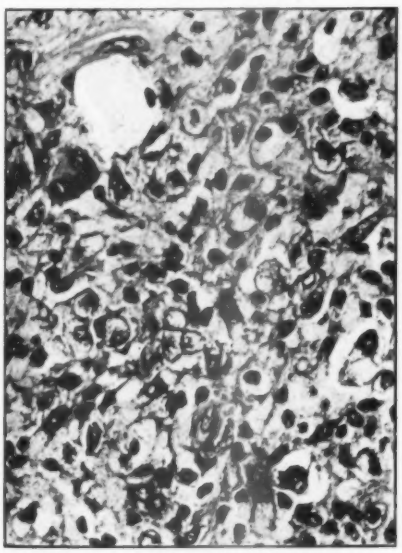

FIG. 2.—× 400. Section after biopsy 14.9.47.

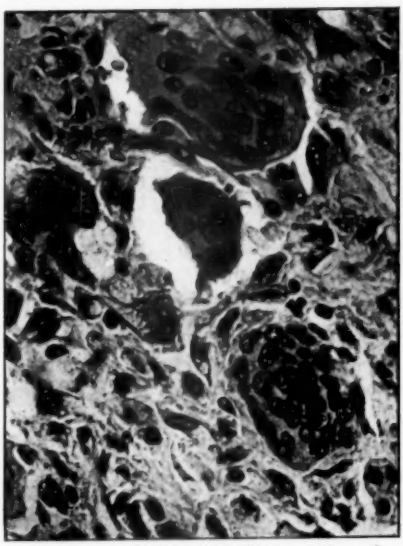

FIG. 3.—× 400. Section after resection of tumour on 15.3.48.

She was given a full course of X-ray therapy. Radiograph on 29.1.48 showed further destruction and a further pathological fracture.

On 2.3.48 the case was shown to this Section as a case of *reticulo-sarcoma*.

15.3.48: Local resection of the tumour: Histological report by Professor Hadfield and Dr. G. J. Cunningham—"Now that we have had an opportunity of examining the whole of the tumour its structure has become obvious. It is a malignant osteoclastoma and shows well-marked infiltration of the surrounding muscle. There is actual destruction of bone by tumour tissue which is not producing bone, but which has a typical osteoclastomatous structure" (Fig. 3).

She has regained good use of the elbow and so far there is no evidence of a recurrence of the tumour.

Osteochondromatosis of the Shoulder.—JOHN ADDISON, F.R.C.S., for J. S. BATCHELOR, F.R.C.S.

D. K., male, aged 31. Bookbinder.

History.—Six years ago had gradual onset of a dull aching pain around the right shoulder with no history of trauma or infection. This pain has persisted, with some remissions, and is worse after work and during cold weather. The shoulder has gradually become more stiff, and has occasional attacks of locking associated with sharp pain. He is left-handed and his disability is moderate.

Physical signs.—There is a little muscle wasting, but no point of tenderness. Crepitus is felt on movements—all of which are limited by 15° to 30°. X-ray (Fig. 1) shows

FIG. 1.—Radiograph.

FIG. 2.—Arthrogram.

multiple loose bodies, particularly in the inferior part of the joint, in the subscapular bursa and in the synovial extension around the long head of biceps. An arthrogram (Fig. 2) demonstrates uneven filling of this sheath and shows its unusual length.

HAGEMANN, R. (1913) *Med. Klinik.*, **2**, 1293.
JONES, H. T. (1924) *J. Bone Jt. Surg.*, **6**, 407.

Sir Thomas Fairbank said of the cases of osteochondromatosis he had seen there were two perhaps worthy of mention. One was a middle-aged woman with a hip-joint affected. The loose bodies consisted entirely of cartilage, with no calcification or ossification, and they were faceted like gall-stones. They were packed so tightly in the joint that the neck of the femur was indented by them and appeared to be cystic in the radiograph. Some of the bodies had to be dug out of pits in the femur. The number actually collected was 163. As usual in these cases there were no arthritic changes. The other case was a colonel, one of whose ankles had been swollen for twenty years. He complained of difficulty in putting on a top-boot. On separating out the masses of loose bodies, which were of the usual type, over 60 were counted.

Tarsomégalie.—R. H. METCALFE, F.R.C.S.

Photographs of X-rays of an ankle of a boy of 10 years of age were shown. These revealed multiple loose bodies, gross overgrowth of the internal malleolus, and premature fusion of the epiphyseal line of the lower end of the tibia. Mr. Metcalfe suggested that this was probably a case of osteochondromatosis, but Sir Thomas Fairbank pointed out that the case was a very rare condition of which only one case had been previously reported in the literature under the title of "tarsomégalie" (Mouchet, A., and Belot, J., 1926, *Journal de Radiologie et d'Électrologie*, **10,** 289). He further mentioned that Mr. David Trevor was publishing a series of eight cases (*Journal of Bone and Joint Surgery*, February 1950) showing similar changes in various parts of the lower limbs and was suggesting a new and more comprehensive title.

Chronic Osteitis of a Lumbar Vertebra (Shown for Diagnosis).—R. C. F. CATTERALL, F.R.C.S.

A. A., male, aged 41. A meter-reader.

History.—Had a fall in 1944 and sustained a fracture of the transverse processes of the lumbar vertebræ for which he wore a plaster jacket for several weeks. Following this accident his back was never comfortable and in May 1947 he sought further advice. He has since obtained relief by wearing a brace.

On examination.—General health good. There is slight limitation of movement in all directions by pain. No local tenderness. No referred pain. Blood chemistry within normal limits. X-ray appearance shows increased density of the second lumbar vertebra as the only abnormality (Figs. 1 and 2).

FIG. 1.—A.P. view of second lumbar vertebra. The bone shows a uniform increase of density, with exaggeration of the internal architecture. The shape of the vertebra is normal, and the adjacent disc spaces are not affected.

FIG. 2.—Lateral view confirms both the bone change and the absence of any arthritic changes.

Mr. J. S. Batchelor: I have a patient, a middle-aged woman, who is complaining of backache, the X-rays of whose spine show sclerosis of the second lumbar vertebra. In addition, she has changes typical of Paget's disease in the lower end of the femur.

I feel that the sclerosis of the lumbar vertebra in Mr. Catterall's case is almost certainly due to Paget's disease.

Subsequent discussion considered and rejected the possibility of malignant disease and angioma as diagnoses, nor was further support forthcoming in favour of Paget's disease.

In summing up, the **President** quoted a similar case of his own which he had called "non-specific osteitis" and had treated with a bone graft.

Curettage of Tuberculous Vertebral Disease in the Treatment of Spinal Caries.—M. C. WILKINSON, M.B.

Impressed with the improvement that may follow costo-transversectomy in the treatment of vertebral caries with paraplegia, both in the patient's general condition and in the vertebral bodies at the site of operation, I have tried to apply a similar method to the treatment of tuberculous disease of the spine without paraplegia. The importance of the abscess in producing persistent disease has been emphasized by Swett *et al.*, 1940. Especially is this so in the dorsal region, an area for which the prognosis is worse than in other regions (Wilkinson, 1949). At operation the abscess is opened by removing the vertebral portions of one or two ribs, including the rib heads; the abscess is evacuated and any loose sequestra or osseo-caseous material are curetted away with a spoon; curettage should be in a forward direction away from the theca. The most important risk is that of tuberculous meningitis, due probably to direct spread to the brain through the perivertebral plexus of veins (Batson, 1940). The administration of streptomycin before operation and afterwards for at least a month should diminish this risk. Especial caution is required in applying this operation to children, owing to the increased risk of tuberculous meningitis.

Two results in adults are reported; streptomycin was only available in small quantities at the time their operations were performed.

CASE I.—W. B., male, aged 45 years. Admitted on April 1, 1946, suffering from tuberculosis of the eighth and ninth dorsal vertebræ and treated for a year in a plaster bed. Nearly a year after discharge he developed fresh girdle pains. Fig. 1 shows unsound ankylosis between the remains of D8 and 9 with surrounding caseo-necrotic material. After two months' constitutional treatment, costo-transversectomy of the tenth rib and transverse process was performed, but there was difficulty in opening the abscess. The rib was minced and inserted into a gutter made in the spines. A month later, in July 1948, costo-transversectomy of the ninth rib and process was performed; a calcified abscess and the lesion in the vertebræ were curetted. The wound healed without sinus formation. The patient was up in a brace four months after operation and returned to work eight months after operation. Fig. 2 shows the spine eleven months after operation. There is bony ankylosis between the remnants of D8, 9; the surrounding osseo-caseous material has been removed.

In February 1949 some progressive caries in D7 was noted, requiring readmission.

CASE II.—V. S., male, aged 30 years. [X-rays only shown at meeting.] This patient had been treated for slowly progressive disease of the tenth and eleventh dorsal vertebræ since 1944. He was in a plaster bed for eighteen months, but was readmitted in 1948 with a very large perispinal abscess, increase in the caries, and poor general condition. Fig. 3 shows caries of D10, 11, 12 with multiple vacuolated areas; the large perispinal abscess was only visible in the A.P. view. Costo-transversectomy of the eleventh rib and process was performed in July 1948, a considerable quantity of fluid pus was evacuated and the eleventh vertebral body was partially curetted. The rib was minced and inserted into a gutter in the vertebral spines. The patient was discharged after four months. He gained 2 st. in weight and returned to full work.

A slight sinus has persisted. Fig. 4 shows the recalcification and re-ossification in D11 due to breaking down by curettage of fibro-caseous barriers, revascularization and re-ossification. Improvement in D10 and D12 is also seen. The A.P. view showed disappearance of the abscess.

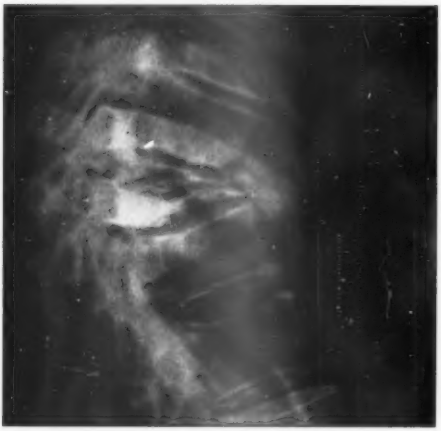

FIG. 1.—W. B. (10.4.48). Chronic caries of D8, 9 after a year's treatment in a plaster bed and a year ambulant in a brace.

FIG. 2.—W. B. (3.6.49). D8, 9 showing bony ankylosis eleven months after curettage of lesion. Patient on full work.

FIG. 3.—V. S. (4.6.48). Chronic caries of D10, 11, 12 of four years' duration.

FIG. 4.—V. S. (12.5.49). Appearance eleven months after drainage of large perispinal abscess and curettage of D11. Patient on full work.

Improvement following operation, but not cure, is all that is claimed for these two patients.

Recurrent Dislocation of the Left Patella Medially.—W. E. TUCKER, M.B.E., F.R.C.S.

E. P., female, aged 13½.

Present history.—At age 11, early 1946, while sitting, left knee dislocated with acute pain. It reduced unaided, and no pain resulted. Repeated inward dislocations started two to three months afterwards and reduction was easily performed.

In January 1949, left patella dislocated more frequently and became painful and more difficult to reduce. Occurred when walking, standing, sitting and turning in bed.

In June 1949, loss of sensation in all left toes following "pins and needles" in leg and foot. Reduction now had to be aided.

There is no history of a definite injury, and dislocation is always to the inner side. Patella now dislocates two to three times daily at times.

On examination (21.9.49).—The left knee was slightly puffy. Movements were full; slight creaking on movement, but no sign of an internal derangement. No undue laxity of the knee, and the quadriceps were normal. The legs were straight.

The radiograms taken showed no bony abnormality.

This case was shown for opinion as to the correct treatment.

Mr. A. S. B. Bankart said that in the past recurrent dislocation of the patella had been attributed to abnormal laxity of the quadriceps, and attempts had been made to treat it by shortening the quadriceps tendon. In this case there was obvious wasting of the quadriceps, and this should be treated first. Should operation become necessary, a fascial sling from the patella to the outer femoral condyle, as described by Gallie, would appear to be the most suitable.

A Polythene Substitute for the Upper Two-thirds of the Shaft of the Femur.—H. J. SEDDON, D.M., F.R.C.S., and JOHN T. SCALES, M.R.C.S.

(This case was reported in *Lancet*, 1949 (ii), 795.)

President—S. COCHRANE SHANKS, M.D., F.R.C.P., F.F.R.

[*October* 21, 1949]

Problems in the X-ray Diagnosis of Cancer of the Stomach

PRESIDENT'S ADDRESS

By S. COCHRANE SHANKS, M.D., F.R.C.P., F.F.R.

I HAVE chosen as my subject for this Address a problem which constantly engages the anxious attention of every radiologist—that of the *X-ray diagnosis of early cancer of the stomach.* In a case of cancer of the stomach there occurs, on an average, an interval of three months between the onset of a patient's symptoms and his first visit to his family doctor. There is a further interval of three months—and this is truly deplorable—between the first visit to his doctor and full clinical and radiological investigation in hospital. When you add to these six months the earlier months during which the cancer was present but caused no symptoms, it is clear why we so often find at the first X-ray examination cancer in a developed or advanced stage. If that is true, one might ask where is the problem, since the patient does not come to us in the early stage.

But some cases do come to us early, and these we must strive painstakingly to detect.

In a cancer of the stomach certain features may give rise to difficulty in radiological diagnosis, as in the case of:

(*a*) A very small lesion.
(*b*) An unusual type of lesion, such as a plaque.
(*c*) A site that is difficult to examine completely.
(*d*) Pre-existing deformity of the stomach, such as hiatus hernia, or cascade stomach.
(*e*) Lesions of the pyloric region.
(*f*) The ulcer-cancer problem.

(*a*) *The very small lesion.*—This is the type so anxiously searched for, and so rarely found. Obviously, a growth at its inception may be too small to be seen, but this is not why one is hardly ever found in an X-ray department. At that stage they are symptomless. Even in malignant degeneration of a peptic ulcer the cancer element gives no evidence of its existence at first. I have already mentioned the time lag between onset of symptoms and examination. How helpless we are therefore to entice the early symptomless cancer into our departments for examination. Russell Morgan in the U.S.A. has launched a scheme for mass miniature barium meal radiology of the population over 40 years of age. Already he has picked up a certain number of unsuspected early gastric cancers. But is this a practical scheme? To be a really efficient sieve, the examination should be repeated every six months, which would need an immense organization, if applied to the whole population over 40 years of age. There comes a point in the national economy when further social benefits cannot be afforded, and in this Country we are over that point already.

But to return to the small lesion, as a rule the chance of detecting this is in direct ratio to the ease with which the mucosal pattern is studied, and I have no hesitation in stating my view that in the investigation of the stomach itself the technique of the complete filling by the barium meal has had its day. Berg's aphorism "The less you give, the more you see" is undoubtedly true if one is searching for a small cancer of the stomach. Fig. 1 is a case in point. This small irregularity in the greater curve was noted and discounted by a very expert radiologist. Looking at the film I agreed. It was, however, an early cancer, and a detailed mucosal pattern study might have revealed the truth. The next case (Fig. 2) showed a slight irregularity of the lesser curve. This was reported as malignant, but operation was refused. Ten months later a gross lesion was evident on X-ray examination.

(*b*) *The unusual type of lesion.*—An instance of this is the carcinomatous plaque, which may produce an appearance indistinguishable from a localized hypertrophic gastritis. Often it is simply not possible to differentiate between the two. The X-ray feature is a localized patch of coarse irregular gastric rugæ. A diffused coarse pattern involving the whole stomach is unlikely to be a growth. In such case search closely for further commonest cause of this mucosal reaction, a peptic ulcer. If no ulcer is forthcoming, reluctantly dub the condition hypertrophic gastritis, and ask for gastroscopic confirmation. In any case of the slightest doubt beg the clinician not to accept your verdict without repeated critical examination. Fig. 3 illustrates a case in point, that of a highly strung, highly efficient, hard-working, hard-drinking, business man of 45, whose stomach I have X-rayed at intervals for five years. Note the appearance in 1944; the filling defect of the pyloric antrum and the antral ulcer, both suggesting a neoplasm. Against this was the coarse pattern in the fundus, and the simple nature of the lesion is shown by an unchanged appearance five years later. Schindler states that hypertrophic gastritis cannot be diagnosed with certainty by X-rays. Many cannot, it is true, but others, including this case, do give definite X-ray signs. Fig. 4 is of another case in which the mucosal pattern suggested a carcinomatous plaque. Gastroscopy (which should always be carried out if the patient can be persuaded to swallow a gastroscope) showed a hypertrophic gastritis which has improved under medical treatment. It will inevitably relapse, and the patient will haunt the O.P. and X-ray clinics till someone takes her stomach out. The reverse picture is illustrated by the next case (Fig. 5). There was a short history of dyspepsia in this man of 62. The X-ray shows a coarse mucosal pattern and a small ulcer niche high up on the greater curve. The surgeon did a transthoracic gastrectomy, and the lesion was proved by biopsy to be malignant. And Fig. 6 shows another in which the carcinomatous plaque high up on the anterior wall was detected only after painstaking search. Fortunately, the search was stimulated by a classic history of recent anorexia, loss of weight, and epigastric pain. Again, in the next case the first picture, in 1942, shows what looks like a healed L.C.U., but with interrupted rugæ (Fig. 7). Malignancy was suggested in the X-ray report, but operation was refused, and in 1946 the patient died of starvation from a stenosing growth (Fig. 8). Note that this patient lived for four years after her cancer was first diagnosed. Had she had her stomach out at the outset and then lived four years the surgeon would reasonably have taken credit for prolonging her life.

(*c*) *The site difficult to examine.*—In this group I give pride of place to the cardia and fundus. It is a region inaccessible to radioscopic palpation and an exhaustive study of the mucosal pattern is often not possible. Add to that normal irregularity of the mucosal pattern, compared with the ordered symmetry of that of the lesser curve, and the difficulty is obvious. The cardia and surrounding fundus are blind spots to the gastroscope, and so an important corroboration may be lacking. Time was when missing a cancer in this region wasn't all that important. The patient was doomed, anyway. Now, with transthoracic œsophago-gastrectomy a satisfactory

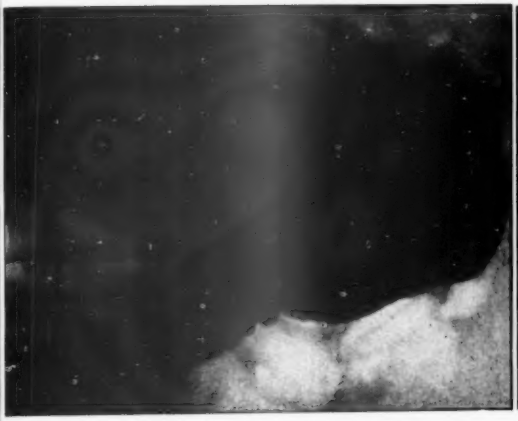

FIG. 1.—Early carcinoma of the stomach verified at operation. The only sign in this picture is the irregularity of the greater curve in the pars pylorica, at first mistaken for a pressure defect from gas in the transverse colon.

FIG. 2.—Early carcinoma of the pyloric antrum, involving the lesser curve.

FIG. 3.—Hypertrophic gastritis.

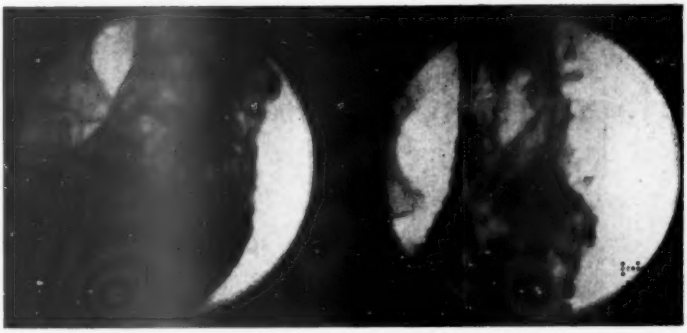

FIG. 4.—Coarse mucosal pattern suggesting a carcinomatous plaque. Gastroscopy and the subsequent history proved it to be due to hypertrophic gastritis.

FIG. 5.—Malignant ulcer high up on the greater curve.

FIG. 6.—Carcinomatous plaque high up on the greater curve.

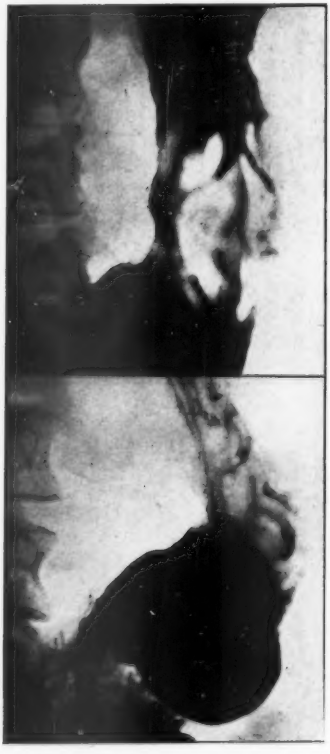

FIG. 7.—Carcinoma simulating a healed lesser curve ulcer: operation refused (*vide* Fig. 8).

operation with a reasonable mortality risk, it is supremely important to recognize growths of and near the cardia in an early stage, when surgical removal is possible.

The classic signs of established carcinoma of the cardia and surrounding fundus are well known: the delay at the cardia, with the loss of the normal intermittent spurt, the splitting of the barium stream, the coating of the tumour mass and absence

FIG. 8.—Same case as Fig. 7 four years later, showing almost complete midgastric obstruction, and reflux œsophageal dilatation.

of a regular mucosal pattern; the outlining of the tumour by the gas bubble, and by the barium in the supine view, and the thickened diaphragmatic shadow above the fundus.

In the early case few of these signs may be present, and it may be extremely difficult to differentiate between an early growth, a hypertrophic gastritis, and an anatomical variation. Rarer causes of difficulty in the differential diagnosis are indentation of the fundus by an aberrant spleen, or by an enlarged spleen in congestive cardiac failure. In one case seen by the writer fibrinous deposit in the left cupola following perforated pyloric ulcer caused a very suspicious fundal filling defect (Fig. 9).

(*d*) *Pre-existing deformity of the stomach.*—The commonest of these is marked cascade stomach, sometimes amounting to volvulus on the transverse axis. A deformity of this type may mask a lesion at the cardia, pars media, or pylorus.

Fig. 10 shows a vague irregularity in a herniated gastric fundus. This proved to be a cancer, and transthoracic œsophagogastrectomy was successfully performed. The presence of hiatus hernia may make the detection of a fundal growth extremely difficult.

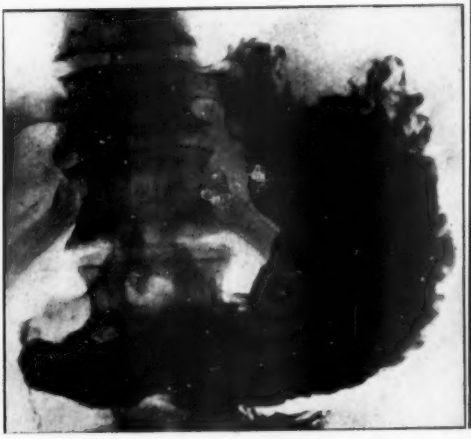

FIG. 9.—Indentation of the gastric fundus by a fibrinous deposit following perforation of a pyloric ulcer. Eight months later the fundus was normal in appearance.

FIG. 10.—Hiatus hernia and carcinoma of the fundus. Transthoracic œsophago-gastrectomy successfully performed.

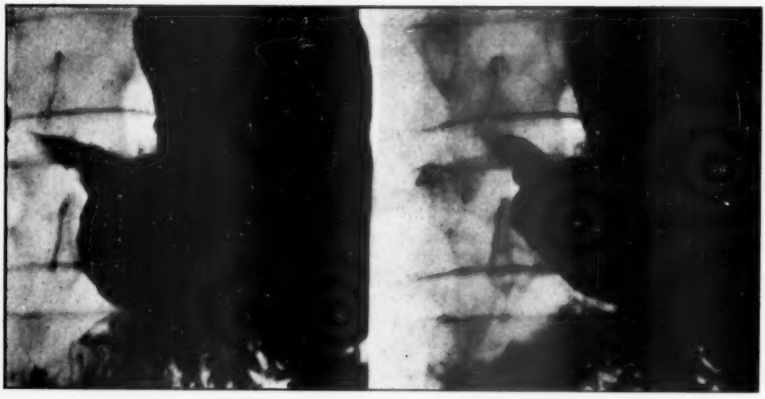

FIG. 11.—Contracted pyloric antrum following posterior gastro-jejunostomy, simulating scirrhous carcinoma.

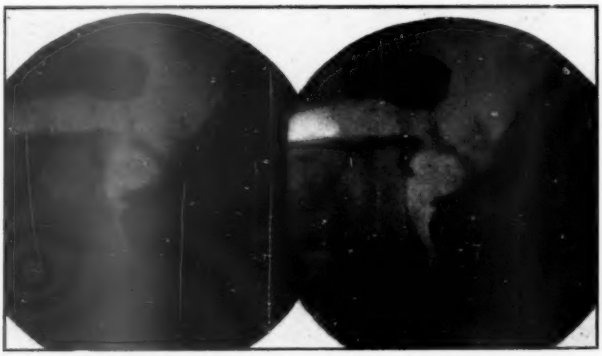

FIG. 12.—Spasm and gastritis of pyloric antrum simulating stenosing carcinoma. For details *see* text.

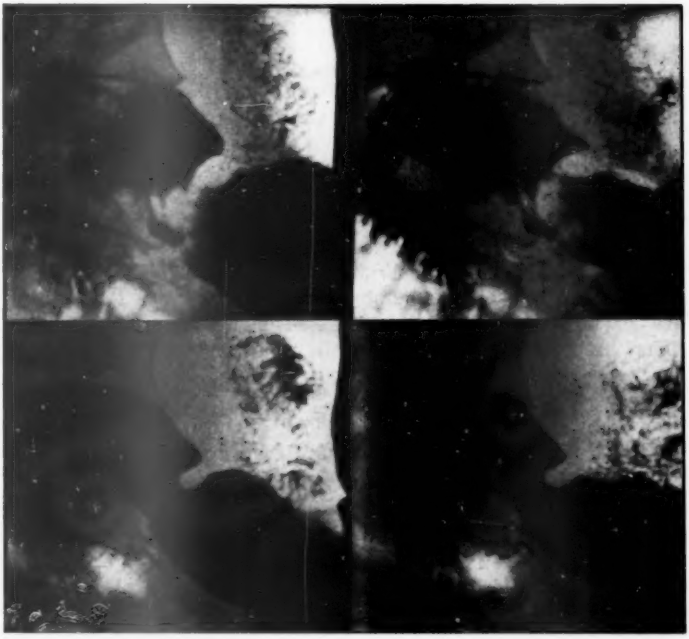

FIG. 13.—Ulcer of the greater curve, near the pylorus (upper two pictures). Its site raised the suspicion of malignancy, but the two lower pictures, taken two months later, show the ulcer completely healed.

A further difficulty arises in the pyloric region after posterior gastro-jejunostomy. The pyloric antrum may become contracted and aperistaltic, and simulate a growth, as in the case shown in Fig. 11 which had the classic syndrome—anorexia, macrocytic anæmia, and loss of weight.

(*e*) *Pyloric lesions* are notoriously difficult to disentangle. The site is a common one for hypertrophic gastritis, and an uncommon one for simple ulcer. It is a still more common one for cancer. Often radiography can show the lesion, but not its precise nature unless by serial examination over months, and gastroscopy may be of great help in doubtful cases. The case seen in Fig. 12 illustrates this difficulty. The filling defect of the pyloric antrum shows the classic appearance of a stenosing carcinoma. At operation an inoperable carcinoma was diagnosed by the surgeon, and gastro-jejunostomy performed for incipient obstruction. A year later the patient was X-rayed, and a jejunal ulcer was found, but no sign of a carcinoma of the pyloric antrum, and a year later still a partial gastrectomy was performed for duodenal and jejunal ulceration. The biopsy confirmed the simple nature of the lesion. Ulcers on the pylorus are usually suspect. So are those on the greater curve. Fig. 13 shows one on the greater curve, and near the pylorus, and yet the pictures taken after two months (below) show the ulcer to have healed later. Fig. 14 shows an almost exactly similar ulcer crater in the pyloric antrum, towards the greater curve. This case was gastroscoped, and the suspicions of malignancy confirmed. At operation there were no clinical signs of malignancy, but partial gastrectomy was performed on the radiological and gastroscopic appearances. On section a few carcinoma cells were found in the adjacent muscle coat, and in an excised lymph node.

(*f*) *The ulcer-cancer problem.*—A carcinomatous ulcer can arise in two ways: (i) ulceration of a carcinomatous nodule or plaque, and (ii) malignant degeneration of a simple peptic ulcer. Much controversy has raged around the frequency of the latter.

C. H. Mayo, Wilson and MacCarty (1924) of the Mayo Clinic propounded the view that many cancers supervened on simple peptic ulcer. This view is supported by Moynihan, Sherren, Pauchet and Maingot. Ogilvie and Schindler hold the contrary. The last mentioned states that in the long series of simple gastric ulcers he had gastroscoped serially over years, he has never met one that became malignant.

The weight of pathological evidence is against the theory. Although the pathologists at the Mayo Clinic stated that 68% of apparently simple ulcers showed microscopical evidence of cancer, such authorities as Ewing, Dible, Spilsbury, Cameron and Newcomb have placed a different interpretation on the histological appearances. As Spilsbury put it: "There are commonly found at the edge of the ulcer gland cells which have penetrated deeply into the scar tissue and are cut off from the regenerating glands. They may exhibit an atypical glandular arrangement, or may form narrow columns of cells: isolated cells are also seen. It is these cells detached from the regenerating epithelium and buried in the fibrous tissue of the ulcer which are sometimes referred to as precancerous, and which, from their position and irregular arrangement, are regarded by others as indicating malignant transformation of the ulcer". Newcomb's criteria for the pre-existence of a simple peptic ulcer in an ulcerating carcinoma are as follows: (1) Complete destruction of an area of muscle corresponding to the floor of the ulcer; (2) the presence of a large area of dense fibrous and granulation tissue in the floor; (3) the presence of endarteritis obliterans in the surrounding vessels; (4) fusion of the muscularis mucosæ with the muscular coat at the margin of the ulcer. Of these by far the most valuable is the last, and it is the only certain evidence that a cancer has arisen from a previous simple ulcer. Using this criterion, Newcomb found that only 13% of cancers showed evidence of an antecedent peptic ulcer, and that 3–7% of ulcers showed a malignant change. Matthew Stewart's figures (Table I) are of interest in this connexion.

TABLE I.—ANALYSIS OF 733 STOMACHS SURGICALLY EXCISED FOR CHRONIC GASTRIC ULCER OR CANCER, 1921–1940 (MATTHEW STEWART)

Independent chronic gastric ulcer	459*
Independent cancer	230*
Ulcer-cancer	51
Incidence of Ulcer-Cancer	
Total stomachs with chronic ulcer	510
Ulcer-cancer 51 (10%)	
Total stomachs with cancer	281
Ulcer-cancer 51 (18%)	

*In 7 instances, unrelated ulcer and cancer were present in the same stomach.

Certain clinical evidence is also against the peptic ulcer cancer sequence being a common one. The average history of symptoms in peptic ulcer is about five to seven years; in cancer it is about six months. If the majority of cancers supervened on simple ulcer one would have expected a longer history in the cancer groups. Again, the great majority of simple gastric ulcers are on the lesser curve, while the pyloric antrum is the site of election for a cancer.

It seems, therefore, that the theory of frequent degeneration of a simple ulcer into a cancer should be abandoned. That it does occur, as in chronic ulcers elsewhere, is undoubted, but most authorities believe that not more than 6% of chronic ulcers become malignant, and that not more than 10–15% of gastric cancers arise from chronic ulcers. Curiously, it never seems to occur in duodenal ulcer, a much more chronic type.

Carcinomatous ulcer.—To determine whether a gastric ulcer is simple or malignant may be one of the most difficult of radiological problems. Often it is impossible to say from the X-ray features alone.

If ulceration occurs in an already existing tumour mass of some size, the signs of the mass itself will make the diagnosis clear, and it is in the cases of malignant degeneration of simple peptic ulcer, or ulceration of a small tumour, that the chief difficulty arises.

In making a differential diagnosis, the following points should be considered:

Size.—Any ulcer larger than 2·5 cm. in diameter should be suspected as malignant until it has been proved to be simple. The larger the ulcer the greater should be the suspicion. Many large ulcers will, in fact, turn out to be simple, but the maxim is none the less a sound one.

Fig. 15A shows a large one that was simple, and Fig. 15B one that was malignant.

Shape.—The simple ulcer tends to be hemispherical, regular in contour and sharply defined. Malignant ulcers tend to be irregular.

Meniscus sign.—Kirklin has drawn attention to an appearance, named by him the meniscus, seen in many malignant ulcers on and near the lesser curve. It is a translucent zone a few mm. in width, separating the barium-filled crater from the main barium mass in the stomach, and is due to the hard-growing malignant edge of the ulcer. Some chronic simple ulcers show the same appearance, if they have a very raised œdematous edge. Fig. 16A shows a meniscus sign in a malignant ulcer, and Fig. 16B an almost identical appearance in a simple ulcer. Some say that the malignant meniscus is intra-luminal, while the meniscus of simple ulcer is on the contour line. This is by no means invariable. A simple ulcer on the posterior wall close to the lesser curve may produce an intra-luminal meniscus.

Site.—This is of importance. Simple ulcer is usually on the lesser curve, distant from the pylorus. A malignant ulcer is variable in site, but most commonly on the lesser curve near the pylorus. Those on the greater curve—they are uncommon—are nearly always malignant.

Therapeutic test.—This is of great value in differentiating the two types. A simple ulcer should heal in a few weeks under medical treatment, a malignant one will not. Again there is a reservation. A malignant ulcer may also, for a time, get smaller during treatment for peptic ulcer. Hellmer records four such cases. He ascribes the

diminution to resolution of mucosal œdema, scirrhous contracture, and/or filling of the crater by tumour tissue. The serial X-ray examinations should therefore continue till the ulcer has disappeared and for some weeks after, to make sure that it does not reappear.

Rugæ.—In simple chronic ulcer these tend to converge to the crater. In malignant ulcer they are said to be interrupted without converging. This again is not always the case. In simple long-standing chronic ulcer which has undergone malignant degeneration the rugæ may converge to the crater, as a result of scarring.

If, after careful survey of all the above X-ray features, there is doubt (and there often is), the radiologist should not hesitate to say so. The anamnesis, the clinical features and gastroscopy will all afford further evidence, and as a last resort surgical exploration may be necessary. It is far better to cure a simple ulcer by partial gastrectomy than to miss a carcinoma.

Fig. 17 is of a case X-rayed by a colleague, who showed the case to me. We both agreed that there was undoubtedly a very large posterior wall ulcer present. It looked a cast-iron certainty, and its size and the lack of complaint of dyspeptic symptoms by the patient, a neurotic middle-aged woman, pointed to malignancy. Yet on laparotomy by an extremely competent and careful surgeon, nothing whatsoever was found—an entirely normal stomach. What caused this extraordinary pouching of the gastric wall is a mystery to me and all concerned.

What conclusions would I suggest from these observations? Firstly, that radiology is the simplest and easiest method of showing an organic lesion in the stomach, and should have first place after clinical examination in the investigation of a suspected gastric carcinoma. In the majority of cases, alas, the diagnosis is all too clear, for the majority of cases are not investigated till the disease is advanced. In many of the early cases, however, radiology can show the lesion, but not its nature. And in these cases, I would make a strong plea for the routine use of gastroscopy. Were the gastroscope easier to swallow than the barium meal, I think it should take first place in the investigation of all gastric cases. If all these methods, clinical, radiological and gastroscopic, fail to give the answer, surgical exploration is the last resort, and biopsy will reveal the mistakes of all.

Finally, may I make one comment on Ogilvie's recent and erudite article on the early diagnosis of cancer of the stomach, in which he says that we should accept the negative warnings of a penny weighing machine in preference to the positive assurance of the ten guinea Harley Street expert. Surely it must be very rare for the combined activities of the clinician, radiologist and gastroscopist to fail to find any lesion of the œsophagus or stomach in such a case. If they do fail they are not entitled to the appellation of a specialist of Harley or any other street.

While I am convinced that the X-ray method remains the most important method of examination in the investigation of gastric cases, it is, nevertheless, only one weapon, and by itself liable, in some cases, to mislead. The final decision must remain with the clinician, who in his gastric clinic must have available all ancillary methods at his disposal, radiology, gastroscopy, clinical pathology and the weighing machine, if he is to be successful in dealing with this most difficult problem, the detection of early cancer of the stomach.

Intracranial Suppuration

PRESIDENT'S ADDRESS

By JULIAN TAYLOR, C.B.E., M.S., F.R.C.S., F.R.A.C.S.

I SET about choosing my subject by trying to decide what section of neurological surgery seemed to have made most noteworthy advances during the war period. Not that I consider wars as characteristically productive of progress, indeed the opposite is more generally true, and much has to be unlearned with the advent of what is called peace. But the lot that I drew in our country's service was an unheroic one (as a prisoner in Malaya), a mole's task that withdrew me from all contact with world progress, arrived though I was at the time of life when a surgeon should survey with detachment and discrimination the march of surgical advance. Released at length from, shall we say, an obligatory search for the Way of Nirvana, and not having seen any of the rapid evolution of chemotherapy and the antibiotics, I was at once amazed at the claims for success that were now made in the management of acute cerebral abscess by chemotherapy. After some deliberation, therefore, I have chosen the subject of Intracranial Suppuration for this Address. The term connotes a large number of sites and of varieties—only a few of which I shall discuss.

Almost since the advent of antiseptic surgery we have known of varieties of abscess, for example some of the otitic ones, that are amenable to treatment by drainage; we have had some good results with sinus phlebitis, and, with the passage of years, we have come to an understanding of the management of certain cases of suppurative meningitis (1941, *Proc. R. Soc. Med.*, **34**, 447).

The subject of Acute Abscess of the Brain, formerly unspeakable unless by a few bold spirits like King of New York, is now a congenial one with the pleasant supporting sense of the confidence of accomplishment, and this blessing we owe entirely to Sir Alexander Fleming and his associates.

I shall discuss briefly some of the varieties of suppuration.

SUPPURATIVE MENINGITIS

Meningitis of otitic origin.—It was known long before the introduction of modern chemotherapy that many cases of otitic meningitis were amenable to treatment of the causative inflammation of the middle ear, a good example being acute extradural abscess complicating mastoiditis and associated with meningitis. If the extradural abscess were drained one had a good chance of clearing up the meningitis. It used to be stated that if there were organisms recoverable from the cerebrospinal fluid, the prognosis was bad, but otherwise good though the fluid might be turbid with pus. This was only the roughest of guides and had many exceptions. Indeed, it was at that time noted in the post-mortem room that when otitic meningitis was there displayed, there could commonly be found no gross and obvious bony destruction that led from the ear to the meninges. A route of infection was demonstrated by Logan Turner, using serial sections of the temporal bone, to be that of a phlebitis of the small communicating veins. Our early conception of the cause of mortality was that of an essential poverty of resistance by the meninges, and we are to some extent confirmed in this view when we realize that where we have a process of disease like that of extradural abscess, there exists an anatomical barrier that may hold up its passage and provide some delay while resistance may be organized on the meningeal side. Where, however, the extension uses the route of small veins passing right across the arachnoid space such a delay may not occur. The former may well be thought to promote arachnoid adhesions early, in the latter their formation may be too late. Now we know that an important part of the defences of the meninges is the process of localization by the formation of arachnoidal adhesions. But at once we must face the problem presented by the almost universal practice and sporadic success, of repeated lumbar puncture, a procedure that must of necessity disseminate the infection that the body, using adhesions, is apparently trying to confine.

This, I think, is a fair statement of the confusion of our ideas about the time when we began to receive the benefits of chemotherapy.

Put broadly, however, we did know that in some patients the meninges seemed to possess a vigorous power of resistance and on the whole those patients whose resistance seemed to

be most efficient, were those who had chronic mastoid disease followed by acute exacerbation with meningitis. This is exactly the kind of evidence that led Trotter to state that the tissues of the mouth and pharynx develop their own local resistance to the infections that infest these cavities, a conception that has since then been verified I believe by bacteriological means. Meningitis, however, is a diseased state in which maximal clinical effects are referable to the arachnoid and to the tissues neighbouring on it, but it cannot be considered as a pathological entity without also taking into account the simultaneous affection of the brain. To the possibility of the elaboration of local resistance I shall return later in connexion with abscess of the brain. Before leaving meningitis I should like to refer to one striking character. It is the protracted duration, the slow tempo, the lingering death, with few signs of toxæmia until the last stages, that we so often see, or rather saw, in surgical meningitis. It seems that the body has provided a powerful resistance to the virulent organisms of the accessory sinuses, perhaps one that might be more completely efficacious elsewhere, but it also seems that in the physiological circulation of the cerebrospinal fluid there has been provided so free a dissemination of infection that the arachnoid is often not quite able to defeat it.

The treatment of suppurative meningitis is now a matter of appropriate chemotherapy, and as an identical therapy is also appropriate to abscesses of the brain, I postpone reference to its practice. Suffice it that what at one time had seemed to be a defect in the defences of the meninges is now an essential part of their armament. The defensive has now luckily taken the form of an offensive.

Infective sinus phlebitis.—In this disease again we have an infective process involving a circulating fluid, but its clinical evolution is a very different one, for it is characterized by severe intoxication, the septicæmia of dissemination. Just as occurs in meningitis, an important part of the body's resistance is to be seen in the process of coagulation, indeed it is the existence of inflammatory clot that provides the diagnostic signs, and should its production fail the true nature of the disease may remain unrecognized. In sinus phlebitis, the efficiency of the process of clotting is greater than in meningitis, and if we give it the slightest assistance, for example, by ligating a big venous trunk, but one which cannot possibly prevent all circulation back to the heart from the source of infection, we may sometimes effect an immediate cure of the septicæmia, one that gives the body the opportunity of time for the clearing up of the local infection. If blood may be said to be the best bactericide that we know, its clotting may be an equally efficient arrest of dissemination. We now turn to the pathological effects of thrombosis on the tissues draining into the sinuses.

When transverse sinus phlebitis occurs we often note the appearance of signs, for example nystagmus, that indicate cerebellar involvement, and also evidence of the existence of meningitis, further evidence of the importance of the diffusion of infection in the central nervous system by the venous system. We sometimes speak a little loosely of œdema of the brain and of meningism.

To elucidate the nature of these effects we may well examine the visible changes associated in the living with phlebitis of the cavernous sinus. This sinus receives blood from the orbital, the dural, and the cerebral veins, and constitutes "a bottle neck". But the bottle neck character of the cavernous sinus is shown by the intensity of the orbital signs when the sinus is the seat of the phlebitis, for the orbital tissues swell as do the eyelids, and the eye is displaced forwards. The conjunctiva becomes so greatly swollen that it projects from between the lids like a noisome tropical fungus, the state known as chemosis. At the same time the eye and the dilated pupil become fixed, though sight is preserved. We may perhaps be tempted to regard these occurrences as the effects of venous obstruction, but if venous obstruction has any part in their pathogenesis it is a very small one. They are the consequences of an inflammation spreading through the walls of the veins large and small, and are thus a true cellulitis. The clotting power of the blood being a rapid function precedes the bactericidal effect, and thus we have a whole venous system clotted and full of active but immobilized organisms. In the case of the cavernous sinus, the immobilizing of the infected blood is not completely efficient, for we know that in the pre-chemotherapy days, if the patient did not die of septicæmia as he might do, he would succumb to meningitis later, the infection spreading to the meninges using the venous route. The following example of this disease supports these views:—

One of my prisoners developed an acute exacerbation of chronic left mastoiditis, an extensive osteitis of the petrous bone, with a left sixth nerve palsy as part of Gradenigo's syndrome. His mastoid was treated expertly by Major Farmer of the A.A.M.C., but nevertheless the infection spread to the left cavernous sinus, and there then appeared on the left side all the orbital signs described, with high fever and rigors. But he did not die rapidly of septicæmia. Indeed, I think there must have been something unusual in the character of their resistances, for among these soldiers septicæmia, often unexplained, was not at all uncommon, and its course was apt to be unnaturally long before they died of it. This soldier began to improve generally, and the eye began to recede so satisfactorily that doubt was cast by some on the correctness of the diagnosis. In about ten days the left orbit and eyelids were of natural appearance, the eye movements almost normal, the angry look of the eye was gone,

and the conjunctiva, no longer swollen, had withdrawn itself between the lids. But soon, as usual, the other cavernous sinus became affected, and the right orbital contents displayed the same series of acute effects as had earlier the left. When this was at its height, he developed obvious meningitis confirmed by lumbar puncture, and in a few more days he died, but not before the orbital signs on the right side were showing slight signs of subsidence. Post mortem, the right cavernous sinus, that later affected, was full of infected clot, but on the left side, where, I will repeat, the orbit had exhibited all the changes characteristic of cavernous phlebitis but had re-assumed normal appearances, the cavernous sinus was an abscess, a sac of pus. It was now a complete obstruction to venous flow, yet the inflammation being now restricted to the sinus itself, the orbital contents had been normal for days. It is remarkable, by the way, that the oculomotor nerve passing through the pus-filled sinus had recovered from paralysis, though it is true that similar observations may often be made elsewhere in the body. Now it may be that modern chemotherapy has, in the civilized state, abolished sinus phlebitis, this is certainly the only example that I have seen in a good many years. But, in the future, should we meet with cavernous phlebitis, it is probable that we shall cure it both as regards septicæmia and meningitis. I am now suggesting that, keeping in mind these considerations regarding the true nature of the orbital changes, we may also look forward to a return of the orbital contents to the normal.

Abscess of the brain.—It is now time to turn our attention to the suppurations of the brain itself. The subject is well divided for clinical, and until recently for therapeutic purposes, into three main groups, the Acute, the Subacute, and the Chronic. It may also be subdivided according to site, and again according to origin, whether the consequence of local or of hæmatogenous invasion. As in the case of the meninges, there has been a conception fixed in our minds for many years that the brain as a tissue has poor resistive powers in relation to bacterial invasion. Again it is doubtful if such a belief is in accordance with facts, for the brain tissue varies greatly in behaviour among the component varieties of the sub-groups. During the past fifty years, there have been recurring waves of opinion favouring treatment by aspiration at one time, by excision at another, but rarely have neurological surgeons advocated the operative drainage that forms a part of the treatment of abscesses employed by general surgeons nearly everywhere else in the body. This is peculiar, because it seems that a measure that is necessary everywhere else is unnecessary in the brain, the lesser procedure of aspiration being, as is made certain by a study of the literature, all that has been necessary in some surgeon's hands. Something similar may be found in the history of the treatment of thoracic suppuration, the treatment of acute empyema by drainage having been for long subjected to criticism and attempts having been made to substitute aspiration. Even with the advent of sulphonamide therapy, however, the general impression was that drainage was eventually necessary, though I am unable to say what is the attitude of the thoracic specialist with the chemotherapy now available. Yet we had for many years the curious theoretical juxtaposition of the brain, a poor resister, and the lung and pleura, a better, yet the first could be treated by aspiration in the hands of some, the second needed eventual drainage according to everyone. There is another undoubted fact that we should not forget, it is that a numerically large proportion of all cerebral abscesses have been treated successfully by otologists who have commonly used some form of drainage. Study of the writings of neurological surgeons, however, suggests that though this therapy has undoubtedly been successful, it may perhaps have been unnecessary, and the minor procedure of aspiration might possibly have been adequate. A third fact of importance is that certain neurological surgeons have recommended the procedure of immediate excision of acute abscesses at early stages in their formation, and have achieved success by so doing.

If, therefore, for abscess of the brain, three different therapies have been successful, varying from aspiration of pus, the least disturbing, to early excision, the most disrupting of the natural healing processes, the only possible logical deduction is that the brain must have inherent in it the capacity of dealing effectively with suppurative infections. The undoubted difficulty that we have all experienced with abscess of the brain should therefore be a technical one, the problem to be solved being how are we effectively to give to the brain the assistance that it always seems to need. There are grave difficulties in accepting our proposition, of which perhaps the greatest is our notorious ill-success before the advent of penicillin, in dealing with metastatic abscesses following on chronic suppuration in the chest.

There is one variety of intracranial suppuration that in my experience the otorhinologist has usually been quick in referring to the neurological surgeon, it is the acute form that so often follows acute frontal sinusitis, and it is deservedly sinister by reputation. It has for long been one of our greatest difficulties, and has so often been fatal that many of us came to regard it as near to hopeless.

Acute suppurative encephalitis.—The ordinary result of the drainage to the surface by, for example, a tube, of such an acute abscess as we are considering, was a large fungus consisting of swollen brain riddled with multiple foci of suppuration. Further, when such an abscess results from frontal sinusitis, the infection seems to pass inwards over a large area

regarding no natural anatomical barrier. The frontal bone is widely infected by osteitis, the inner wall of the sinus has no appearance of having been penetrated, but the infection may then be found everywhere, in the subdural space, in the arachnoid space, and in the brain where it quite soon arrives at the ventricular system.

Here then is stated our problem of acute suppurative encephalitis and it is indeed a formidable one. Some courageous spirits, however, were not intimidated, and the solutions offered have been varied.

Leaving out for the moment the question of the coverings of the brain, the surgeon's sound reaction to a spreading acute infection is to await localization, and thus the practice of repeated aspiration until an anatomically thick and therefore palpable wall should have been formed, has had many adherents in the past.

The variation practised by Clovis Vincent was a temporary osteoplastic decompression, followed by repeated tapping, and by removal in the end of the abscess when localized. But it may well be that localization may not be sufficiently complete or rapid and that the patient may succumb during the waiting period. Nevertheless the need to secure localization of the infective process as revealed by the formation of a dense and palpable abscess wall remained for some of us the controlling factor for many years, however we might deal with the treatment of the later stages.

Another solution was that of King of New York. He temporarily rolled up the scalp, removed large areas of infected bone, and then uncapped the suppurating mass of brain tissue, opening it to the surface as an acute cerebral ulcer. He laid especial stress upon the closure of the arachnoid spaces by diathermic coagulation, i.e. by a method that infallibly killed the linings of the space at the place of closure. Using such methods, he had no fear even of intraventricular rupture of an acute abscess. A fistula into a lateral ventricle was to him a far simpler affair than was the problem presented by the pathways of the arachnoid space.

Both the skull and the brain were thus treated by the excision of a so far quite unlocalized suppurative infection, and extension in the meninges was prevented by the provision of a block in the arachnoid space consisting of charred, dead tissue. That an infection spreads disastrously on account of poverty of resistance by intracranial tissues, and that it can be arrested by such measures are to my mind incompatible beliefs. Something was wrong with our premises for there is no doubt that King was highly successful. What is to my mind shown clearly here is that what was once considered a poor resistance was not intrinsic in the brain substance. It was imposed on it by its physiological mode of nutrition and the anatomical paths of the arachnoid through which this is carried on.

I mention King's name because he was a pioneer and because I had the great privilege of seeing his work at close quarters. But I intend no discourtesy to the arduous and successful labours of many others to all of whom acknowledgment is not possible. Let us nevertheless honour these for they have insisted on saving their patients' lives undeterred by theoretical objections.

I think that we should now be able to come to certain tentative conclusions about abscess of the brain.

(1) The first is that the brain has a considerable power of resisting such infections, whatever the nature of such a resistance may be.

(2) The second is that failure to cure these patients has been due to operative measures that have not been successful in preventing dissemination in the cerebrospinal fluid space. Included in the cerebrospinal fluid space is the brain substance and the ventricular system.

(3) I add a third suggestion which is not a conclusion, it is only an opinion. It is that where we have a chronically infected bone like the petrous in otitis media and mastoid disease, the brain develops a local resistance to the infection that fits it to deal with gross penetration of the dura when it occurs, either as the result of a phlebitic process or by the necrosis of suppuration.

The solution of the problem.—The discovery of penicillin and its application to the treatment of cerebral abscess have solved the problem of its management where the causative organism is penicillin-sensitive, and the solution applies to all such forms of abscess.

Sir Alexander Fleming and Sir Hugh Cairns and his Oxford followers have given us precise information regarding the distribution of the drug and its concentration in blood and cerebrospinal fluid when administered in various ways. But I wish here to say a little about the reason for its amazing success in the central nervous sytem. We have already seen that the principal difficulty in the management of abscess of the brain is to be found in the dissemination of the infection in the cerebrospinal fluid space, but now at last we are freed from the need to attempt to prevent this. For with penicillin the less obstructed the arachnoid space, the clearer the path open for the diffusion of the drug. Further we must remember that the cerebrospinal fluid not only circulates in the arachnoid space, it also perfuses the brain substance, and it is this fact that enables penicillin to destroy infection in the brain with the completeness and certainty that characterize its action. Thus that which was a disability imposed by a nutritional method has become an essential means by which our

curative drug is diffused. It follows that our method of giving the drug must comply with the needs imposed by its path of distribution. In order that it will reach for certain every infected tissue when dealing with suppurative processes in the brain we must start our penicillin on its course as near as possible to the place where the cerebrospinal fluid begins its journey. Fortunately this is easy by the method of ventricular puncture. Systemic penicillin therapy has also a function in these diseases, it is the treatment of the focus whence the central nervous system was infected. Its indications thus vary with the nature of the primary disease.

The following cases treated by myself and my assistant, Mr. Bernard Harries, each illustrated some part of our problem:

(i) Subacute abscess of the brain.
(ii) Chronic abscess of the brain.
(iii) Abscess metastatic from chronic thoracic suppuration.
(iv) Acute suppurative meningo-encephalitis.

(i) *Subacute Abscess of the Brain*

Boy aged 9 referred to me by Dr. Blake Pritchard.

History.—Pain in the right ear two months before present illness. Fourteen days before we saw him he had fallen down in the street and subsequently had malaise with shivering, still later right frontal headache and vomiting.

On admission to University College Hospital he presented head retraction, drowsiness, nystagmus, cerebellar signs in the right arm and leg. Lumbar puncture produced clear fluid containing 132 cells per c.mm., 75% of which were polymorphonuclear, the remainder lymphocytes. The right ear-drum was reddened and there was inspissated discharge in the meatus.

Operation.—A diagnosis of right cerebellar abscess had been made by Dr. Pritchard on November 2, 1948. A burr hole was made behind the bend of the right transverse sinus and a needle put into the abscess from which a few cubic centimetres of pus were aspirated. No firm wall was felt. 20,000 units of penicillin were instilled into the abscess cavity. Both lateral ventricles were tapped and penicillin was instilled into one of them twice daily to begin with, later once daily for three weeks. Systemic penicillin was also given as treatment of the otitis media. The abscess was explored with a needle on two later occasions, and on the second, three weeks after the operation, no fluid was obtained. No organisms were ever grown from the pus.

The boy made a good recovery and is still well. This is the kind of cerebellar abscess that in the pre-chemotherapy days I should have treated by means of tube drainage, and I should have been surprised had he not recovered. The same applied to very many cases of otitic temporal abscess. A drain, however, always results in scarring of its track, and a needle is far better.

Comment.—This boy had a chronic otitis media, and when he developed cerebellar abscess the infecting organism was so greatly attenuated in virulence that it failed to grow in a medium. His cerebellum and the arachnoid which the infection had crossed undoubtedly had developed a strong resistance and perhaps it was a locally developed one. In the days of tube drainage, it was the custom of the majority of surgeons, no doubt with the doctrine of low resistive power in mind, to leave these tubes in for long periods. Such treatment must result in scarring anywhere in the body, and a scar probably matters more in the brain than elsewhere. I always doubted the need for this prolonged drainage though on occasion I have been intimidated into maintaining it for a few weeks. It is quite possible that this boy could have been adequately treated by aspiration alone, by penicillin into the abscess cavity alone, or by intraventricular penicillin alone.

(ii) *Chronic Abscess*

Girl aged 9.

History.—For nine months she had had intermittent headaches which for two months had been very severe and accompanied by vomiting. Before the headaches began she had had a pain in the ear, had been examined by an otologist who noted a reddened drum. For some time a diagnosis of otitic hydrocephalus had been accepted and the child had been treated by repeated lumbar punctures and systemic penicillin. But the disease had speedily progressed and the child had recently become so much worse that a diagnosis of cerebral tumour had been made.

On examination she was drowsy, there was a right external rectus weakness, right facial weakness, bilateral upgoing great toes, and absent abdominal reflexes. There was a high bilateral papilloedema. Ventriculography showed that the right lateral ventricle was dilated and displaced to the right. The left lateral ventricle could not be filled.

Operation.—A diagnosis of large left temporal chronic abscess was made. A burr hole was made in the lower left parietal region just behind the ear. At a depth of 4 cm. an abscess with a just palpable wall was encountered and 38 c.c. of thick yellow odourless pus were aspirated. The ventricles were again tapped the left one being now found. 100,000 units penicillin were instilled into the abscess and into the ventricle. Daily ventricular penicillin was instituted and the abscess cavity reaspirated on several occasions, penicillin being instilled. On the last occasion no pus was found, only a drop or so of clear fluid.

Five weeks after her operation ventriculography showed no abnormality and her papilloedema and other signs had disappeared. Again no organism was grown from the pus. Again a powerful resistance had been developed.

Comment.—About this child I should not have been at all confident in the pre-chemotherapy days. Drainage of a cavity 4 cm. from the surface of the posterior temporal lobe has elements in it both of inefficiency and of the danger of infected fungus. In such a position

I should not have considered excision, for it must have been followed by hemiplegia and aphasia. This child recovered rapidly and is now well, taking daily luminal. She had a chronic abscess. It has not been excised and I do not anticipate further trouble unless it be the onset of epilepsy. Had, however, this abscess been situated elsewhere in the brain, it is just the sort of one that many surgeons would deem it proper to excise, though possibly as a secondary procedure.

(iii) *Hæmatogenous Abscess Secondary to Chronic Thoracic Suppuration*

This kind of abscess has had in the past a truly evil reputation. The late Mr. Tudor Edwards told me that he had never known one recover, and so bad were the results that there were good physicians of great experience who preferred to leave these patients alone, hoping for the natural temporary subsidence of symptoms that sometimes did occur.

Here is a typical example. Among the sailors nearly but not quite drowned at the sinking of the *Prince of Wales* on December 10, 1941, was a petty officer who contracted pneumonia and then an empyema. This was drained by a surgeon, but unluckily inefficiently, because through the tenth rib, and he developed a chronic sinus. After temporary healing, about a year later he came to see me as a prisoner and in our so-called hospital we drained his cavity more suitably, later doing a small operation of the Estlander type. After this all went well until one day about a week later he said he could not see to the left. It did not disturb him as he could read, but an examination of his visual fields showed that he had a left homonymous hemianopia with preservation of the whole macula. We made a little hole in the right occipital region and encountered with a needle some white inoffensive pus in the brain at a depth of less than 1 cm. from the dura. We thought the prognosis hopeless. We put in a drainage tube. All seemed to be well until after the lapse of a few days he complained one morning that for the first time he could not read, and, as expected, we now found that the homonymous defect passed vertically through his macula. I explored his brain again and found the abscess larger. His state became steadily worse and he died. Post mortem his whole right occipital lobe was seen to be a bag of pus with no visible abscess wall other than the grey matter. The extent of the abscess could not be accurately determined because in addition to there being no lining, the brain was decomposing in the tropical climate of Singapore, but the following may be the explanation of the progress of the visual changes.

Macular representation is usually held to lie in the posterior part of the occipital cortex, exactly where I found the abscess on the day it first caused symptoms when macular vision was still unaffected. But it has been held that there is bilateral representation of the macula in the occipital cortex, and it has also been stated that the path of the contralaterally destined fibres lies in the posterior part of the corpus callosum. If this be correct anatomy, it is possible that the macula at first escaped while the abscess was still small, but when it grew to the size seen at post-mortem, it may be that the advantage of bilateral representation was lost as the result of affection of the fibres passing from the right radiation to the unaffected left occipital cortex. I refer to this patient because he exemplifies what I have noted as a major difficulty in attributing strong powers of resistance to the brain. Here was a brain in a not grossly emaciated man whose other reactions to infection seemed to be natural, which clearly opposed no defence at all to the spread of an infection, for his abscess seemed to be nothing but a spreading quiet necrosis whose macroscopic limits could not be recognized. I should not have quoted it at length, had it not had much in common with what we were accustomed to see in such cases at home before the war. Now, however, things are very different, as the following account makes certain. In March 1947 a man aged 27 was admitted to University College Hospital suffering from progressive drowsiness of one or two days' duration. He had suffered from bronchiectasis and four years earlier a lobectomy had been performed. He was semicomatose. There was right facial weakness, absent abdominal reflexes, weakness of the right arm and leg with down-going great toes, there was no papilloedema. His cerebrospinal fluid from lumbar puncture showed a pressure of 300 mm. and slight turbidity. An immediate ventriculogram showed the body of the left lateral ventricle narrowed and displaced to the right and upwards. A left parietal abscess was then aspirated, no organism being grown from the pus. Penicillin was given as in the other cases into the abscess which had no palpable wall at all and into the ventricles, and he made a progressive recovery.

A month later no further pus could be obtained. Eighteen months later he professed himself perfectly well except for a further exacerbation of his bronchiectasis.

Such a recovery was a new thing to me though I am glad to say that it is not now a solitary example.

I now turn to the last and most serious of my groups, the catastrophe of

(iv) *Acute Suppurative Meningo-encephalitis*

In my hands before the war this disease had been invariably fatal, though I believe that others have been more successful. In October 1948, however, a boy aged 13½ was admitted to the Royal Ear Hospital suffering from acute *left* frontal sinusitis and left maxillary antritis. The left antrum was irrigated and systemic penicillin was given, under the direction of Mr. Formby and Miss Wadge. After a lapse of two weeks he was better though an occasional slight evening fever was noted. His frontal headache then returned and he began to vomit, but there was no further discharge from the nose. There was neck rigidity, Kernig's sign, and a slight *left* lower facial weakness. The cerebrospinal fluid from lumbar puncture showed a pressure of 180 mm. water and was a little turbid. Later he had a rigor, became drowsy and developed a *left* extensor plantar response. The fluid was now more turbid and contained large numbers of pus cells. His state rapidly deteriorated, and two days after the onset of cerebral symptoms, Mr. Formby and I explored both his frontal sinuses. Neither contained any pus or fluid, but the mucosa was dark and œdematous. The dura was exposed on each side, no extradural abscess being found. A small exploratory cut was then made in the dura of each side. On the left side, the side on which the frontal sinusitis was known to have existed, nothing was found and the opening was closed. On the *right* side a collection of thick pus was found in the

subdural space. Its extent could not be estimated, but seemed to be wide, and the depth of the lake of pus was not more than 2 or 3 mm. This *right* subdural space was drained with a thin soft tube. Double ventricular puncture was performed. The ventricles were clearly small. On the *left* side I had a little difficulty in finding the ventricle for it seemed to be smaller than on the right. During search for the left lateral ventricle the needle was withdrawn, and a drop of pus from the brain substance in the left parietal region was aspirated. The fluid in the ventricle when it was entered was in small quantity, was viscid and turbid.

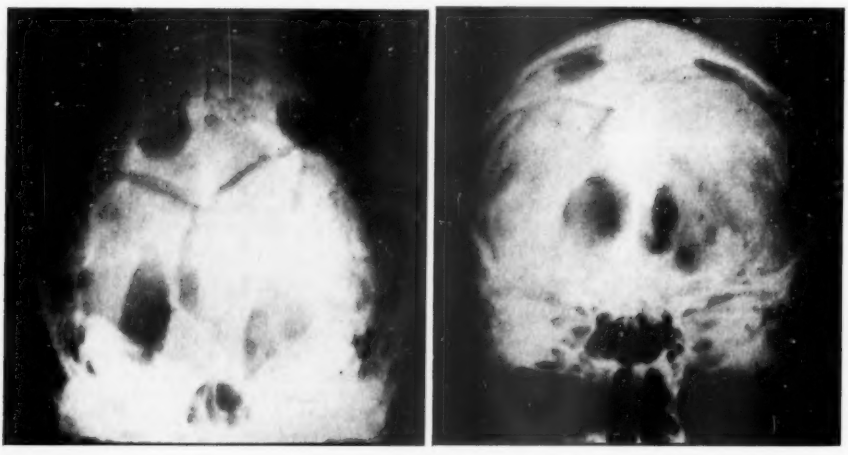
The frontal sinuses were left open, and treatment by ventricular, by lumbar, and by systemic penicillin was instituted and sulphamethazine was also given. The pus yielded a *Streptococcus viridans* on culture.

The case was regarded as probably hopeless, he lapsed from drowsiness into coma, and then needed tube feeding. After some days he began to show some signs of improvement. When he recovered consciousness he had complete aphasia for a day or so, and later began to throw right-sided Jacksonian fits. Pus had practically disappeared from his lumbar fluid. A fortnight after his operation a ventriculography was done which showed now some dilatation of the ventricles with displacement of the ventricular system to the right. A burr hole was now made in the *left* temporal region, and a large collection of subdural pus was encountered in the temporal and parietal regions and was drained. He then began to improve more rapidly, his fits ceased and he began to lose his aphasia. He remained in hospital for some months gradually improving, and being given luminal. He was discharged apparently well. In May 1949, six months after his operation, he came to hospital suffering from generalized epileptic seizures. Contrary to instructions, his luminal had not been taken after discharge. A ventriculogram was now normal, luminal was again ordered and no further fits have been seen.

Here was a patient suffering from meningitis, from subdural abscess over the right hemisphere, from swelling of the left and suppuration in its substance. Later a subdural collection over the left hemisphere also was found and drained. A clearer example of diffuse suppurative meningo-encephalitis cannot be imagined yet apart from epilepsy he has made a complete recovery. It calls for no comment save an obeisance to Sir Alexander Fleming, for no surgeon could have helped this boy without penicillin.

These few cases are selected for description as exemplifying types, from about ten successful ones, treated on these lines. I have, however, lost three. The first was a lady with acute suppurative meningo-encephalitis, who at post-mortem appeared to have succumbed to septicæmia and pneumonia, her cranial contents being apparently then clear. The second complicated a chronic empyema and he died, I think, because I succeeded in aspirating only a few cubic centimetres from a large abscess. The third had a deep-seated parietal chronic abscess, alongside the falx, with a thick wall that I did not succeed in penetrating with my needle. It burst somewhere into the cerebrospinal fluid space, and he died. Both these last two deaths were certainly associated with, and it is likely were due to, technical failure on my part.

I think it is fair to say that we have now a successful treatment for all grades of virulence and chronicity of abscess of the brain due to penicillin-sensitive organisms. I have no experience of streptomycin in these cases because it has been unnecessary and naturally one prefers the less irritating drug. Before ending I should like to say just a little about cicatrices in the brain.



The method we employ is always distribution of penicillin in the central nervous system by repeated ventricular puncture, beginning sometimes twice daily then continuing for a space once daily. We have had no trouble with our punctures which are almost painless once the incision has been made and closed. It has been recommended that a canula should be tied into the lateral ventricle. I do not think that this can be said to be a sound procedure, for a foreign body cannot be kept *en demeure* without causing some necrosis. If we tie a catheter in the urethra for a day, we get urethritis however cleanly be our methods. If we keep a needle in a vein we get thrombosis. It is the custom nowadays quite light-heartedly to keep tubes in the œsophagus for long periods, but I have seen linear ulcers in the thoracic œsophagus many inches long in the post-mortem room following such therapy. Now we are beginning to learn that among the many patients who survive such measures, there is an increasing incidence of benign stricture of the lower œsophagus. I cannot help thinking that if we tie a canula in the brain substance we shall get a line of necrosis at its site. Recently in the case of a child suffering from hydrocephalus following the treatment of tuberculous meningitis by streptomycin, a canula was tied in a lateral ventricle contrary to my instructions, not, I hasten to say, by one of my assistants, for even now, in these days of control by registrars, I have some slight influence over their activities. A cerebrospinal fistula resulted that had to be closed by operation, and an air picture demonstrated the track that the necrosis made. We have seen nothing similar with ventricular puncture repeated once or twice daily for weeks.

I feel sure that the members of this Section will support me in the view that every scar in the brain is a danger, and the bigger the scar the greater the likelihood of its causing epilepsy. In the surgical treatment of the brain therefore a prime consideration of every surgeon should be that all scarring that is not absolutely necessary should be avoided.

This brings me to the question of excision of abscesses. I have many times excised chronic abscesses in the past, but with penicillin I am sure I shall not do so often in

the future. Yet a study of the literature of the present day cannot fail to show us that just now the wave of opinion is in favour of the excision of abscesses, almost as routine. I do not say that a cerebral abscess need never be excised, but I know for certain that excision is usually unnecessary. I think that perhaps the demonstration of loculi by the use of radio-opaque substances injected into the cavities of abscesses has something to do with the urge to excise. I should like here to point out that to inject a foreign body such as thorotrast, or an iodine oil, or any other opaque substance, into a closed abscess cavity is asking for persistence of the infection as plainly in the brain as it would be anywhere else in the body. There is no primary reason to suppose that it may be any less provocative of chronicity than is a sequestrum, or a knot of so-called absorbable catgut, in the depths of a sinus. I cannot help thinking that the widespread habit of demonstrating the existence of abscesses radiologically by this means may be a cause of the need to excise them late. Last year I was consulted by one of our nurses at University College Hospital. Some time previously she had had a frontal abscess treated by a neurological surgeon whose name is famous, for whose work I have nothing short of reverence, and whose permission I have to discuss her case. She had a small opening in her frontal bone, and she would frequently come to me with swelling of her forehead and eyelid—also the slightest headache and a flicker of raised temperature. I sent her back to the surgeon who had saved her life and he agreed that if possible we should do nothing. Eventually he excised the still active cicatrix of the abscess and she has since remained well. The interesting thing is that the site of the abscess was still shown before this last operation by a persistent opacity in the frontal lobe, the shrunken relic of such a radiological demonstration.

Abscesses of the brain may be slow in healing. Here is a pair of ventriculograms. No. I shows displacement of the ventricular system to the left after a right frontal abscess of traumatic origin had been drained and was apparently soundly healed. I thought we had another and needled the brain fruitlessly at an unnecessary operation. No. II shows what another

No. I. No. II.

FIG. 1.—Ventriculogram No. I shows displacement of the lateral ventricles to the left due to swelling of the brain substance persistent after the healing of an abscess of the right frontal lobe. No. II shows the state of the ventricles a month later.

month of leaving the brain alone did for him. The ventricles are now back in their right position. The natural slow resolution of some of its suppurative inflammation is a request from the brain that it be not irritated by the unnecessary injection of foreign substances that it cannot absorb.

Finally, who can doubt that the scarring resulting from a needle and the resolution of an abscess assisted by penicillin, is far less extensive than that produced by the gentlest of excising surgeons.

[The Address was profusely illustrated by slides. Owing to pressure on space only one figure has been inserted.]

[*November* 18, 1949]

The Mechanism of Antibody Production

By C. O. STALLYBRASS, M.D., D.P.H.

FEW subjects have led to more controversy than immunity. The rival theories—cellular and humoral—of Metchnikoff and Ehrlich have been fused in a general Theory of Immunity giving due place to both phagocytosis and antibody production, but the mechanism of antibody production has become almost as controversial an issue as was that of the Metchnikoff-Ehrlich debate. Many hypotheses have been advanced by Manwaring (1928), Breinl and Haurowitz (1930), Alexander (1931), Mudd (1932), Sabin (1939), Burnet (1941), Sevag (1945, 1946), and Northrop (1948), a number of which have been shown in the light of newly acquired data to be inadequate. Recent advances in relation to the biochemistry of genes, viruses, bacteria, and the granular biosomes of cells, point to the important functions performed by nucleo-proteins in vital processes, to which no place in antibody production has been given except a brief reference by Monné (1948).

E. B. Wilson said in 1899 "Nuclein" (meaning nucleo-protein) "may, in a chemical sense, be regarded as the formative centre of the cell which is directly involved in the synthesis of complex organic matters. The specific character of the cytoplasm is determined by that of the nucleus. The nucleus cannot operate without a cytoplasmic field". In antibody production there may be differences between the processes following the introduction of soluble and of particulate antigens, the latter being subject to phagocytosis, but the essential intracellular mechanism involves the interaction between nucleus and cytoplasm which Wilson's intuition foretold.

In propounding any hypothesis of antibody production certain accepted facts must be given due weight:

(1) Free antibodies are modified globulins mainly produced in the reticulo-endothelial system, principally in the cells of lymph-nodes and spleen and probably the skin, but also in the mobile phagocytes. Associated with the experimental production of antibody there is commonly a rise, which may be absolutely greater, of normal gamma globulin in the blood. The spleen and/or lymph-nodes often enlarge concurrently.

(2) The curve of rise of antibody content frequently takes an exponential form, i.e. resembles population increase curves.

(3) Bissett (1947, 1948) showed with frogs that by altering the environmental temperature in the first and second periods of antibody production two distinct and successive mechanisms were operative.

(4) A second injection, given perhaps after all detectable antibody has disappeared from the blood, produces an even more marked response, the so-called "anamnestic" response. This induced antibody-production mechanism may persist throughout life. The stimulating effect of the repeated injection bears only moderate quantitative relation to the amount injected.

(5) Particulate antigen appears to produce a more lasting response than a soluble antigen (Freeman).

(6) Antibodies are specific not only to the antigen but also to the species of animal injected (Heidelberger, 1938). There is a genically controlled specificity of the antibody which the normal globulin inherits and an induced immunological specificity, corresponding with the specificity of the antigen with which it can visibly unite. The mechanism of production of this high and twofold specificity is the crux of the question.

(7) The enzymes involved in synthesis are not self-replicatory.

(8) The same is true of antibodies. Serum globulin injected does not reproduce itself autocatalytically.

(9) Antibody is not produced in appreciable quantity in the absence of living cells.

(10) The antibody produced may far exceed in quantity that of the antigen injected; there is no direct mathematical relationship.

Examination of earlier hypotheses of antibody-production mechanism shows that many of them are vitiated by involving one or more of the following concepts which are either known to be, or probably are, fallacious:

(i) *Incorporation of fragments of the antigen in the newly forming globulin antibody.*—This seems inadequate to permit of the high specificity of the process of antibody production. Moreover as antigens may be polysaccharides, &c., such as gums, entirely foreign to the animal body, such incorporation appears to be metabolically impossible without complete degradation, again with complete loss of specificity.

(ii) *The Buchnerian hypothesis of incorporation of the whole antigen in the antibody molecule.*—This is equally untenable on the grounds just given under (i). Further, as shown by Berger and Erlenmeyer (1931) and Hooker and Boyd (1932), using arsenic-containing haptenes, the amount of antigen was much too small to permit of even a single atom of arsenic being retained in each antibody molecule so produced. This hypothesis must likewise be rejected.

(iii) The concept that the antigen is retained within the cell where its molecule impresses its configuration upon each newly forming globulin molecule. This mechanical coin-and-die comparison, whilst in accord with some facts, appears incompatible with (4) above. It often would involve the retention of the antigen, apparently unchanged, throughout life. Two forms of this hypothesis have been put forward, namely that the "impression" is made either on existing normal globulin or upon a globulin precursor which Northrop (1948) termed a "proteinogen" and Wrinch termed a "proteon". None such has been chemically demonstrated.

As Northrop himself points out (1948) the observation of Dougherty and his colleagues (1944*a*, *b*) made upon malignant lymphocytes of mice will, if confirmed, render this hypothesis likewise untenable. Dougherty transferred such lymphocytes to animals of the same species where they reproduced the disease by rapid cell division; the process was repeated by inoculating serially a new generation of mice with the malignant cells with identical result. The original mouse with malignant lymphocytosis had been injected with a specific antigen against which its lymphocytes contained antibody; the final generation of lymphocytes contained the specifically induced antibody, although the amount of original antigen transferred with each serial transmission must have been excessively small. On these grounds the concept of "moulding" the antibody, or its precursor, appears to fall to the ground.

Burnet's (1941) hypothesis is based upon the seeming similarity of the process of antibody production to that of the production of adaptive enzymes in bacteria. In both cases the presentation of a new and foreign substance, a substrate in the adaptation of enzymes, an antigen in the case of antibody production, evokes a specific alteration in the metabolism of the cell involved. The essential similarity is the modification of an existing enzymic process. Burnet regarded a lasting modification of the intracellular proteinases (kathepsins) by contact with the antigen as operative. If the antigen is contained in a particulate entity, e.g. a bacterium, this must, presumably, first undergo cytolysis, for this process to be effected. Burnet

dismisses the concept of continuing spatial contiguity of antigen and globulin in the mechanism.

Since Burnet put forward this hypothesis great developments have taken place with regard to protein synthesis and structure, to the systems of enzymes involved in carbohydrate synthesis, and to the transfer of energy from the carbohydrate oxidation-reduction cycle to phosphate-carrying co-enzymes. The reversible action of enzymes, such as proteinases, whilst theoretically possible, requires the activity at higher levels where specificity is implanted, e.g. in the formation of polysaccharides of a nucleo-protein; this has been shown, by the work of Griffiths and Avery (McCarty *et al.*, 1946) in the case of specific pneumococcal capsular polysaccharides, to be dependent upon a specific nucleic acid molecule, presumably operating, after transfer, in conjunction with the specific pneumococcal protein as a nucleo-protein molecule.

Whether proteinases can by themselves reversibly synthesize a mixture of the "building blocks", such as amino acids, amines and polypeptides, into specific proteins, is open to question. Chantrenne (1949) considers that acyl phosphates play an important part in protein synthesis. It is in this way that the energy transfers, commonly recognized as essential to synthesis, can be effected (Lipmann, 1941). The not improbable production of amino acids from keto-acids by amination forms a link between carbohydrate and protein synthesis. There are probably other routes available.

In relation to the nucleic acid moiety of nucleo-proteins the structure of some of their component nucleotides, e.g. adenylic acid, is almost identical with some of the co-enzymes, e.g. adenosin diphosphate, and is closely allied to some enzymic phosphatic groups; this relationship seems to indicate a comparable metabolic role, namely, anabolism and katabolism and the simultaneous energy transfers (*see* Schlenk, 1949). There is an accumulating body of evidence that the regularly repeating tetranucleotide structure of nucleic acids, i.e. polymerization, postulated by Levene, is an inadequate representation of the specificity of the nucleic acids, a specificity mirrored in the specific part they play, e.g. in specific pneumococcal polysaccharide synthesis. Nucleic acids were considered by Gulland (1947) to contribute as much to the specificity of the nucleo-proteins as does the protein moiety of those gigantic molecules. Indeed Boivin (1948) has expressed the opinion that every species of bacterium has its own specific nucleic acids.

The characteristic nucleic acid of chromatin (genes) is the desoxyribo-nucleic acid; treatment of cells with ribonuclease removes the corresponding acid from the field and the remaining desoxyribose acid can, by appropriate means, be shown to be a constituent, small, but probably important, of cytoplasmic structures which may be termed generically biosomes; these are divided by cytologists into mitochondria ("fibre-granules"), chromidia, &c., though the lines of division are not always clear (Ludford, 1928; Ludford *et al.*, 1948; Claude, 1941; Bourne, 1942; Brachet, 1945; Monné, 1948; &c.) The presence of ribo-nucleic acid in the cytoplasm, mainly in biosomes, though also in nuclear structures, e.g. chromosomes and nucleolus, is associated with its active proteosynthetic role.

There is, indeed, a general consensus of opinion that ribo-nucleo-protein plays an active part in protein synthesis and that the richness of ribo-nucleic acid content and the intensity of synthesis are correlated (Boivin, 1948).

The metabolic turnover of the ribo-nucleic acid both during growth and during antibody formation is very much greater than that of the desoxyribose acid (Chargaff and Vischer, 1948); Brachet (1945, 1948) from his investigations of the metabolism of developing ova finds evidence to indicate that in the sea urchin there is, within the early hours of development, a rapid conversion of ribo-nucleic acid into the desoxy-acid. How this can be done is not understood and it seems not improbable, in the light of the study of introduction into metabolism of artificial compounds containing radio-active isotopes, that it involves degradation of the lengthy molecules into their

constituent ribo-nucleotides with subsequent conversion into the equivalent desoxy-nucleotides, reconstitution of the nucleic chains, and finally polymerization or end-to-end linkage.

Studies by Harris and Harris (1949) show a parallel increase in ribo-nucleic acid and of antibodies in plasma cells of lymph nodes during immunization, by a peripheral route, but no increase in either when non-antigenic substances are injected. Both Fagraeus (1948) and Ehrich and his colleagues (1949) regard plasma cells as playing a major part in antibody production when the antigen is subcutaneously introduced.

Every hour 200 million lymphocytes enter the blood stream (Trowell, 1947) replacing an equal number which return to the reticulo-endothelial system, there to be destroyed. In Sabin's (1939) ingenious studies of production of antibodies in lymphocytes of animals injected with Heidelberger's dark-red azo-dye antigen, she observed how the dye disappeared from these phagocytes contemporaneously with the production of antibody. Further they were seen to shed a portion of their cytoplasm (exoplasm) into the blood stream; this elegant demonstration of the locale of antibody production in the lymphocytes' cytoplasm is convincing.

The fundamental concept of chemical genetics (Zechmeister and Went, 1948) is that each gene controls a single step in biosynthesis; correspondingly Keilin has shown that the effects produced by an organized system of enzymes differ from the summation of the products of each enzyme acting alone; synthesis is genically controlled and is not haphazard. The genes are efficiently protected from environmental influences by the nuclear membrane. The study of mutants of yeast (Beadle, 1948; Stephenson, 1949) has shown that the loss of a single gene, in relation to amino-acid synthesis, results in an inability to synthesize the acid.

Ludford, Smiles and Welch (1948) have photographed by phase-contrast and ultraviolet light the granules of lymphocytes (mitochondria) which contain nucleic acid which is strongly absorptive of ultraviolet light at 2650 Å, so much so that if over-exposed the light is lethal and they lose their nucleic acid envelope and then no longer reveal its presence. In dividing malignant lymphocytes, where protein synthesis is actively proceeding, these granules can be seen to distribute themselves equally into the two daughter-cells during cell division. They appear therefore to be both proteo-synthetic and self-replicating (*see also* Bourne 1942 *re* multiplication of mitochondria).

Attention has again been directed to such self-replicating cytoplasmic bodies and the manner in which genically controlled structures may receive intracytoplasmic modification from externally derived substances present in the cytoplasm. This, as already stated, is the crux of the problem of antibody production. Such "cytoplasmic inheritance", which in no way affects Mendelian inheritance through gametes, has been postulated again in more precise manner by Sonneborn (1943), Darlington (1944) and Spiegelman (1946). Potentiality for enzyme formation may segregate in Mendelian fashion; such gene-enzyme potentiality may be developed cytoplasmically. Spiegelman and Kamen (1946) find, from their experiments in cells whose enzymic metabolism has been largely inhibited by sodium nitrite, that such *self-duplicating entities in the cytoplasm are nucleo-proteins rather than the enzyme itself.* This accords with the finding that all self-duplicating units are inseparably linked with nucleic acids. By competition with other units within the cells for the building blocks of proteins and enzymes the enzymic constitution of the cell is determined. Darlington terms bodies of genic derivation and cytoplasmic location, controlling molecular activities, *plasmagenes.*

Both the ribo- and desoxyribo-nucleoproteins easily aggregate with phospholipids forming a nucleo-protein-lipid symplex. Spiegelman and Kamen (1946) consider that in adaptive enzyme formation a plasmagene Pl combines with an enzyme precursor Pr and a substrate S to form a symplex PlPrS, resembling the phospholipid symplex termed PLAPS isolated by Miles and Pirie (1939) from Brucella. From such a symplex the new enzyme is derived. This concept is supported by Monod (1944,

1945) who also postulates a common enzyme precursor of species-specific character.

It must be pointed out that the enzyme precursors best known, e.g. pepsinogen, trypsinogen, are unmasked, at any rate in the case of pepsinogen, by a loss of a part of the molecule—about one-fifth. The true intracellular proteinases (kathepsins) are activated (Fruton, 1941) by ascorbic acid or substances, e.g. glutathione, containing sulphydryl groups. The inert precursor appears to be a device to inactivate the enzyme so that it does not act katabolically to the detriment of the cell; some lipid-protein attachments appear to perform a similar function (Monné, 1948).

The occurrence of precursors of enzymes which, or some of which, are proteins—possibly globulins—armed with a prosthetic group, commonly a vitamin, is still problematical in the sense of a species-specific substance which can be moulded into a particular shape upon the presentation of a new substrate. Similar species-specific protein (in this case globulin) precursors such as Northrop's proteinogen and Wrinch's proteon, are even more problematical.

What does appear likely is that the plasmagene—presumably desoxyribo-nucleic acid—ribo-nucleic acid, and the antigen, enter into a symplex and effect the production of a *new plasmagene symplex or system*, with the appropriate enzymes, and control—within the mitochondria or other biosomes—the production of the new globulin, with or without the globulin precursor. The two-stage process demanded by Bissett is allowed for; the exponential curve of antibody production can be explained by (*a*) multiplication of mother and daughter cells containing the new system and (*b*) multiplication of the specifically modified biosomes within those cells. The anamnestic response corresponds to the re-stimulation and renewed multiplication of the appropriate cytoplasmic system, which appears to involve a large increase of ribo-nucleic acid. So stimulated, the intracellular enzymes and building blocks would be diverted largely to the building of the new globulin, but the production of normal globulin would be simultaneously stimulated and a large increase of normal globulin might ensue.

This hypothesis, which it is hoped contains the minimum number of hypothetical activities to accord with the known facts, is not simple, but neither is the normal process of protein synthesis which requires further alteration to permit of the known twofold specificity of animal antibodies; it is based (*a*) on a partial analogy with adaptive enzyme production, (*b*) on the genic activities of nucleo-proteins, and (*c*) those of enzyme systems located in (*d*) mitochondria and/or other biosomes of cytoplasmic location. It is largely a modification of previous hypotheses, notably that of Burnet. So stated it is hoped that it will escape Occam's razor "*Entia non sunt multiplicanda praeter necessitatem*".

Professor J. R. Marrack: *Structure and Formation of Antibodies.*

We are agreed that antibodies are individual globulin molecules that have the special property of combining specifically with molecules of the homologous antigen or haptene. Before approaching the problems of the formation of antibodies we have to consider the structure of globulins and the difference between any antibody molecule and other globulin molecules that gives it the specific ability to combine with the corresponding antigen.

Globulins are proteins and are mainly composed of amino acids combined in peptide chains. The backbones of these chains are made up of the first two carbon atoms of the amino acids and the nitrogens of the NH_2 groups: the "tails" (e.g $—CH_2.CH(CH_3)_2$ in leucine, $—CH_2.CH_2.COOH$ in glutamic acid) stick out from the chain. The chains can be bent and coiled: this bending and coiling is limited, as the tails occupy space and get in each other's way. In the fibres of silk it appears that the C and N atoms of the backbone are approximately in a plane and the chain is not coiled. In the fibres which fall into the α-keratin group (hair and myosin) the chains are supposed to be arranged in a series of loops in the plane of the backbone, each loop consisting of 9 amino-acid residues. The

molecules with which we have to deal are not fibres, but are compact and have been likened variously to balls, buns, eggs and cigars; the chains in these compact molecules must be much more looped or folded than those in the fibres.

Of these compact molecules we know most about the structure of horse hæmoglobin—unfortunately one that is a poor antigen and has been little used in immunology. This according to Perutz and colleagues (Boyes-Watson, Davidson and Perutz, 1947; Perutz, 1949) has a hatbox shape (a cylinder, height 34 Å, diameter of base 57 Å). The hatbox is made of four layers just under 9 Å thick. These layers consist of peptide chains, which Perutz (1949) thinks have small loops, similar to those of the α-keratins, at right angles to the plane of each layer and bends, at longer intervals, in the plane of the layer. The tails of the amino-acid residues lie in the planes of the layers, though some of the longer tails may be bent and stick out from the base and top of the hatbox.

The 4 hæm groups lie on the side of the hatbox, at right-angles to the lengths of the chains; each occupies about 1/40 of the area of the side. The 4 histidine residues, to which the hæm is attached, must therefore lie at the 4 bends of the peptide chains—these being the only positions where the side chains could protrude in the right direction. Haurowitz (1949) considers that the hæm groups are specifically attracted to the globulin molecules by other groups besides the histidine residues. Hæmoglobin molecules, therefore, have specific combining groups at the bends of the peptide chains.

The molecules of other proteins—horse myoglobin, serum albumin, egg albumin and ribonuclease (but not insulin)—appear to be made up of layers, like those of hæmoglobin. One dimension of the molecules of most proteins, as calculated, is approximately the same as the height of the hæmoglobin cylinder. It is possible that the molecules of antibodies and of protein antigens may also be made of layers of peptide chains and that these chains may have loops and bends like those of hæmoglobin. The molecules of antibodies in rabbit and human serum and diphtheria antitoxin of horse serum are usually compared to cigars (prolate spheroids)—length 300 Å, thickness 34 Å. An elongated brick-shape would fit the data equally well. The bricks might consist of continuous layers with peptide chains running the whole length of the molecules or a row of 4 structures with shorter chains. Globulin molecules can be split into halves transversely to the long axis in the first stages of digestion by enzymes; they are not split into layers. The second suggestion therefore appears more probable.

The only forces by which an antibody with such a structure can be bound to an antigen, serum albumin or globulin for example, are (1) Van der Waals' forces, (2) Electrostatic attractions between oppositely charged groups, (3) Hydrogen bonds. These forces are, first, not specific; any two atoms are mutually attracted by Van der Waals' forces; any positive charge attracts any negative charge; hydrogen bonds can be formed between any oxygen, nitrogen or sulphur atoms. Secondly they are short-range forces. The Van der Waals' attraction varies inversely as the 7th power of the distance between two atoms. The force of attraction when the distance is 1 Å is 1/128 the attraction at 0·5 Å. Thirdly, these forces are relatively weak; if therefore only a few pairs of atoms of two molecules can be brought into close contact the attraction between them will be small; if on the other hand a large number of atoms of the two molecules can be brought into close contact the attraction between the two molecules will be strong.

The sides of the hatbox molecule of hæmoglobin and the ends and sides of the brick-shaped molecules of more elongated proteins are not smooth, as the tails of the amino-acid residues project from the surface to varying heights. The tail of a leucine residue may project by about 4 Å (which is 7% of the diameter of the cylinder) and the tail of a tryptophane residue by 6 Å. These tails differ in lateral dimensions. The width of the leucine tail is about 2 Å widening at the end to 3·6 Å; that of the tryptophane tail is about 4·5 Å. There are gaps between these projections. If the projections on the surface of an antigen molecule fit into the gaps on the surface of an antibody molecule the attraction between them will be strong. We therefore believe that the ability of an antibody to combine specifically with antigen is due to the arrangement of the amino acids on its surface in a pattern that fits the pattern of those of the antigen.

We know from work with artificial antigens that the determinant groups of the antigens may be relatively small; the formation of the combining sites of the antibody may, therefore, involve a rearrangement of the pattern of a few amino acids only; but this is not necessarily always the case.

Pauling (1940) suggested that the specific patterns of an antibody might be formed by appropriate coiling of the ends of a peptide chain, after it had been formed. The possible patterns of coiling are limited for steric reasons. I do not think that the number of possible variations of coiling could be enough to provide specific binding sites for all the possible antigens. Incidentally the two ends of a peptide chain cannot be similar, as Pauling appears to assume; there must be a free NH_2 at one end and a free COOH or CO—NH_2 at the other.

It has not been possible to detect any difference between the composition or structure of one antibody and of another, or between antibodies and non-specific globulins. But the analyses have, so far, not been so complete that they exclude such differences.

The groups by which a globulin molecule, which is an antibody, combines with an antigen are distinct from those by which it combines when it is itself an antigen. Thus diphtheria antitoxin (a horse-serum globulin) can combine with toxin when it is also combined with antibody to horse-serum globulin. I suggest that the antibody groups may be on the ends of the brick and the antigenic groups on the side.

We have, therefore, to consider how the introduction of an antigen can induce the appropriate arrangement of the growing antibody molecule. This involves some hypothesis about the synthesis of proteins. There are two theories:

(1) The *template theory* according to which the amino acids are arranged on a template in the correct pattern and then synthesized by a team of enzymes.

(2) The *conveyor belt theory* according to which the growing protein molecule is presented to a series of specific enzymes in appropriate order; these enzymes add the appropriate amino acids from an unselected collection of amino acids.

I do not think the second theory is possible. It would involve the existence of as many proteases with distinct specific activities as there are amino acids; there is no indication of the existence of all these specific enzymes.

The known structure of the hæmoglobin molecule and the theory of the specific character of antibodies emphasize the importance of arrangement in space. It is very unlikely that the peptide chains that constitute these molecules would spontaneously loop, bend and pack themselves into the structures found in the complete molecules. The theory proposed by Dr. Stallybrass seems to me to fail to account for arrangement in space. There must be some kind of template, not only to pick out and arrange appropriate amino acids in the right order in the peptide chains, but also to fold and pack the peptide chains.

According to the template theories of Breinl and Haurowitz (1930) and of Mudd (1932) an antigen is deposited in the places where serum globulins are formed; amino acids are fitted into an appropriate pattern on the antigen, just as the amino acids of the complete antibody fit to the antigen; the amino acids are then synthesized into a protein, which is the antibody. The theory of Pauling (1940) differs in that it supposes that the antigen does not influence the synthesis of peptide chains, but only determines the pattern in which their ends are coiled; it is, all the same, a theory according to which the antigen acts as a template. The recent experiments of Dickey (1949) provide an example of the induction of specific affinity by such a template action. Silica gel is formed by adding acid to a silicate solution which contains methyl orange; the methyl orange is then extracted with methyl alcohol. The gel so formed adsorbs methyl orange specifically. If butyl orange is used in place of methyl orange the gel formed adsorbs butyl orange most strongly, ethyl and propyl orange less strongly and methyl orange least.

I do not think that, so far, the theory as proposed by Mudd and by Breinl and Haurowitz differs essentially from that of Burnet (1941). The template is acting as part of the enzyme system of the immunized animal; it might be called a co-enzyme. The great difficulty, in any theory, is to account for the persistence of the formation of antibodies and of the ability to respond to a second stimulus with a rapid and large formation. A guinea-pig that has been sensitized by a protein may remain sensitive for the rest of its life. An even more remarkable example is the persistence of sensitiveness to tuberculin through several generations of subcultures of the fibroblasts of tuberculous animals (Moen and Swift, 1936). This is the fundamental objection to the theory that supposes that the antigen itself serves a template. Work with isotopes has shown that an animal's own proteins change continually; we can hardly imagine that a foreign protein would persist for long. The amount of tuberculin carried with the first inoculum of cells, in the experiments of Moen and Swift, would be reduced to an ineffective amount after two subcultures. As Burnet concludes, the factor in the enzyme system that determines the specific structure of antibodies must be reproduced in the body of the immunized animal. But it is hardly conceivable that an animal could copy a foreign group such as the *arsonic* acid, which is the determinant group of very efficient antigens.

In accordance with the theory that antibodies are formed by lymphocytes it has been maintained that γ-globulin can be extracted from lymphocytes. Kass (1945) found that a protein extracted from lymphocytes of human lymph glands would form a precipitate with antiserum to human γ-globulin. I have repeated Kass's procedure, using the large lymph glands of a patient who died of Addison's disease. The extract formed a precipitate with antiserum to γ-globulin, but also with antiserum to albumin. The concentration of γ-globulin estimated by the optimum proportions method of Dean and Webb (1926) was about 1/3 of the concentration of albumin and only 1/100 of the total protein concentration in the extract. It is probable that the γ-globulin found was derived from a small amount of serum that contaminated the lymphocytes.

Section of Surgery

President—DIGBY CHAMBERLAIN, Ch.M., F.R.C.S.

[*December* 7, 1949]

DISCUSSION: GASTRODUODENAL HÆMORRHAGE AS A SURGICAL EMERGENCY

Dr. A. H. Douthwaite: I suppose it is in the minds of most of us at this Meeting to consider the indications for surgery when severe bleeding has occurred as the result of peptic ulceration—either gastric, duodenal or anastomotic. I shall not refer to such rarities as benign tumours of the stomach which may cause bleeding, or to carcinoma which is obviously a surgical problem. I do not, furthermore, propose to spend any time on elementary points of differential diagnosis, such as determining whether the blood does, in fact, come from the digestive tract rather than the respiratory passages. There are, however, a few conditions, always unsuitable for surgery, which may give rise to hæmorrhage and a mistaken diagnosis of peptic ulcer. I shall refer only to examples which I have met with in the course of practice during the last twenty-five years and shall not give an inclusive list of the possible diagnostic hazards.

In the first place cirrhosis of the liver may present a great difficulty in its recognition. We must always remember that many of the signs which might be elicited in a patient otherwise well will be masked in one who has bled profusely. The history of indigestion occasioned by the cirrhotic liver and associated gastritis is not always easy to differentiate from that given by a chronic ulcer, and such physical signs as enlargement of the liver and spleen, though helpful when present, cannot be relied upon to save one always from a diagnostic pitfall. When we remember that although the bleeding in cases of cirrhosis usually comes from the varices in the œsophagus, yet it may also come from an actual ulcer in the stomach superimposed on the chronic gastritis so frequently present with cirrhosis of the liver, the extreme difficulty of making a certain diagnosis will be at once apparent. In fact, no matter how careful one is, sooner or later one is almost certain to make the mistake of assuming a peptic ulcer of a chronic nature when none such exists. Even if we had time to carry out liver tests, and even if the patient were fit enough to support these, they are extremely unreliable in anyone who had bled profusely. The effect of a big hæmorrhage is also to cause a reduction in the size of the spleen which might be palpable before the hæmorrhagic incident. A less common mistake, but one of which I have seen three examples in hospital, is to diagnose peptic ulceration and hæmorrhage when the underlying disease is chronic nephritis with uræmia. In these three instances the patients were admitted with a history of recurrent abdominal discomfort for several months and no other symptoms until a profuse hæmatemesis put their lives immediately in jeopardy. Certain points should, however, prevent one from perpetuating the mistake. The patient is always abnormally drowsy for the degree of anæmia, the tongue is always dirty and covered with a brown fur, there is invariably considerable wasting with loss of subcutaneous fat and there is also well-marked thickening and tortuosity of the palpable arteries and usually enlargement of the heart. Even if urine is available it does not necessarily contain an appreciable amount of albumin. Once the condition is suspected a blood urea determination will settle the diagnosis, for these hæmorrhages never occur until the uræmia has reached a level of at least 100 mg. per 100 mil. The cause of the hæmorrhage is a widespread gastritis.

Chronic indigestion as the leading symptom in tuberculosis of the lungs is well known to all of us. Gastroscopy in such cases usually shows a pale œdematous mammillated gastric

mucosa, but it is not perhaps generally recognized that on this account acute ulceration may arise and cause profuse hæmorrhage. A careful overhaul will usually raise suspicion of this unusual event, but I have seen one example in which the patient was opened on the wrong assumption that a chronic ulcer was at the root of the trouble.

The last mistake to which I have to refer is in the case of hæmorrhage due to arterial hypertension. Fortunately this is quite uncommon, but when it does occur it may be very profuse, resembling in that way the persistent epistaxis which is a better known feature of the disease. Here the mistake should not be made because there are always signs of the secondary cardiovascular changes of hypertension and there is never any history of indigestion except perhaps the flatulence common to patients with an overstrained heart.

Severity of hæmorrhage.—It is generally agreed that all figures and opinions relating to the value of surgical or medical treatment for gastroduodenal hæmorrhage are completely useless unless they are given in relation to the severity of the hæmorrhage. Probably the only point of contention between the physician and surgeon relates to severe hæmorrhage arising from peptic ulceration. We all have our ideas of what we mean by severe, but it is difficult to get any criterion generally accepted. Although the hæmoglobin level is not an accurate guide, especially in the first few hours following the bleeding, I think we might take it that any hæmorrhage which has reduced the level to 50% may be regarded as severe. If we watch such a patient over the next few hours and find a slow fall of hæmoglobin but no further rise of pulse rate, no restlessness, no further vomiting of blood or the passage of loose red or reddish-black stools, we can be fairly sure that the hæmorrhage has been brisk but is rapidly subsiding, if it has not already stopped. With efficient medical treatment nearly all these cases will recover. In looking through various records I have collected thirty-five examples such as I have quoted, and only one died. This was a man of 65 with gross arteriosclerosis; two days after the hæmorrhage had apparently ceased he had another brisk hæmorrhage and died within two hours. Efficient medical treatment means an adequate supply of fluid, blood transfusions if the hæmoglobin is 40% or lower, and the securing of rest. Although morphine is the traditional drug to use and I believe the right one, it is a mistake to employ it alone. It causes spasm of the pyloric sphincter, it tends to induce vomiting in many people and does not always induce that peace of mind which is so essential to an alarmed patient. A quarter to half-grain of morphine should be injected together with 2 grains of papaverine hydrochloride and 3 grains of sodium phenobarbitone, the whole given intramuscularly on account of the bulk of the solution. This is far more satisfactory than morphine alone, it is reliable and in my view safe. It might be argued that the fatal case I have mentioned would have been saved by operation. This is doubtful. All surgeons are aware of the extreme difficulty of finding and securing the bleeding point when dealing with a patient with a chronic ulcer. If to play for safety we operated on all patients whose hæmoglobin was in the region of 40%, at least 95% of the operations would be entirely unnecessary and it is doubtful whether they would be free from operative mortalities. It is impossible to decide which of the patients who have bled severely will go on bleeding and which will stop. If, however, we are satisfied that the bleeding *is* continuing we then come to our real problem—the patient whose hæmoglobin is now perhaps in the region of 30% or lower and who is gravely ill. I have notes of 7 patients who at the time of admission or shortly afterwards were so ill as to be apparently moribund. They were cold, sweaty, confused, drowsy, greyish in colour, restless, with an imperceptible pulse and the blood pressure, if it could be measured at all, was below 70 mm. of mercury. Hæmoglobin levels were from 28% to 18%. 6 of these patients died directly as the result of the hæmorrhage. Blood, of course, was given by drip transfusion and it ran out yet faster from the gut. One, who was relatively young, the age being 35, evidently stopped bleeding when he appeared to be about to die, and then recovered in a miraculous fashion. What would have happened if these patients had been operated on? 6 patients in a similar condition, on whom surgery was advised, either by me or others, died, 4 on the table, 2 within an hour of getting back into bed. It is true that these cases go back over several years, and it is only perhaps in the last few years that the importance of giving a really large transfusion has been appreciated. We all agree that the obvious approach to a bleeding point is a mechanical one—that is to say surgery, but the peculiar difficulty in relation to the stomach and duodenum is that in order to get to the point the patient has to be subjected to what is an enormous strain for an exsanguinated body. Then there is the hunting for the bleeding point, the trauma of its exposure, and closure. It cannot be expected that the human body deprived of nearly all its blood could recover in these circumstances. I believe that the solution must lie in our ability to detect earlier the persistence of bleeding in patients who come in after severe hæmorrhage but who do not, as yet, exhibit the signs of collapse I have described. I am coming to believe that in a case of a patient whose hæmoglobin is below 50% and who, in spite of the sedation which I have mentioned, shows a persistently rising pulse rate and falling hæmoglobin, surgery should be evoked promptly. I suspect that many of our deaths

in the past have been the result of undue hesitation on the part of the physician, hoping against hope that the next hour or so will see the patient rounding the corner.

If we could tackle the victim before he reaches the stage of collapse and give him rapid transfusion before and during the operation, and continue with drip transfusion after the operation, surgical results would improve and lives would be saved.

A few words in conclusion on surgery in relation to recurrent hæmorrhage from chronic ulcer. If we are satisfied that there is a chronic ulcer, be it in the stomach or duodenum, and if severe hæmorrhage has occurred twice in the past, I have no doubt that surgery should be instituted in the quiescent period and the source of danger removed by one or other surgical manœuvre. At once, however, the query arises—how do you know that the ulcer is, in fact, chronic? In at least 90% of cases the history is in keeping with the findings and one is in no doubt, but we do meet the 10% where the remarkable absence of history of recurrent indigestion suggests that there is merely an acute ulcer unsuitable for surgery; yet later investigation or even autopsy may reveal a large chronic ulcer as the source of the hæmorrhage. I am sure that this error is largely due to the low intelligence of a certain class of patient, rather than to any peculiar absence of symptoms. I have never met it in the intelligent but only in the classes from whom any history is difficult to elicit. However, the difficulty is, in fact, there. Again, if there has been a history of recurrent symptoms pointing to chronic ulcer and if the presence of a chronic ulcer be confirmed by X-ray, and if the patient be over 55 years of age, or if he has premature arteriosclerosis even though he be younger, then a single hæmorrhage would be, to my mind, an indication for operation when he has recovered from its immediate effects. The few surgical fatalities I have seen from operating on what might be called the "cold stage" of chronic ulcer have almost always been due to the poor general condition of the patients. They have usually leaked blood off and on for months, they are anæmic, the blood urea is raised and there is to be found a disturbance of the serum proteins, notably a fall of the albumin component thus upsetting the normal A/G ratio. These patients look tired, they often have swollen ankles at night, they are hypotonic and the blood pressure is usually in the lower regions of the normal or even subnormal. No matter how anxious such a patient may be to get on with the operation, his persuasion must be resisted firmly. A fortnight's rest in bed, correction of the anæmia, the administration of a high protein diet, or, if necessary, a mixture of amino acids, may make all the difference between life and death when it comes to surgery.

Curare.—My last point is a warning in relation to curare. In the patient such as I have depicted, or in one who is bleeding, I believe that there is a danger in using this drug. It is never necessary in the hypotonic individual. To produce complete flaccidity of the skeletal muscles in an individual whose systolic pressure is probably in the region of 100 or 110 is to invite such pooling of blood in the muscles that although the operation may be technically a success, the patient may die on the table of peripheral circulatory failure.

Mr. Norman C. Tanner: Gastroduodenal bleeding as a surgical emergency resolves itself into three problems:

(1) For *which* bleeding gastroduodenal lesions is emergency surgery indicated? (2) *When* is emergency surgery required? (3) What surgical technique is appropriate when operating for gastroduodenal bleeding?

(1) I will commence by giving a list of the causes of massive gastroduodenal hæmorrhage which I have encountered during the years 1941–1949 at St. James' Hospital, Balham.

TABLE I.—CAUSES OF GASTRODUODENAL BLEEDING (CASES) 1941–1949

Gastric ulcer	364	Simple gastric neoplasm	5
Duodenal ulcer	258	Gastric diverticulum	1
Anastomotic ulcer	40	Pancreatitis	2
Œsophageal ulcer	2	Carcinoma of pancreas	2
Gastritis	53	Aneurysm of aorta	1
Carcinoma of the stomach	29	Uræmia, chronic nephritis	1
Portal hypertension	31	Uncertain, duodenal diverticulum, &c.	44
Hiatus hernia	3		
		Total	836

We will group the first five together, for they all present with similar histories, so that preoperative differential diagnosis is uncertain, and the treatment is similar. In this group I have no doubt that surgery must play a most important part, which I will discuss later.

Carcinoma of the stomach.—Bleeding from operable gastric carcinoma usually ceases spontaneously, and so I prefer to treat these cases medically in the first instance, and then by transfusion and feeding get them into good enough condition for really radical surgery. All those cases of gastric carcinoma which I have found it necessary to operate on as an

emergency, because bleeding did not cease spontaneously, have proved to be inoperable. On the other hand half of the total group were resectable later.

Portal hypertension.—This condition is better treated medically in the first instance, for the majority will cease bleeding spontaneously in the first incident of bleeding. If necessary the balloon of an altered Miller-Abbot tube (Figs. 1 and 2) may be placed in the lower

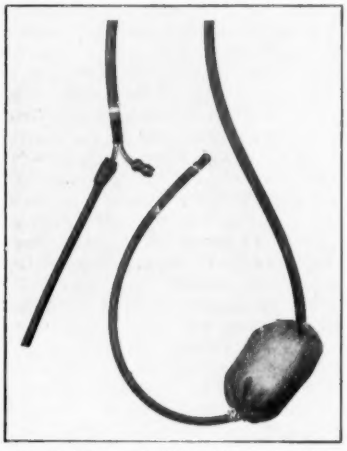

FIG. 1.—Balloon of Miller-Abbot tube altered for use in lower œsophagus.

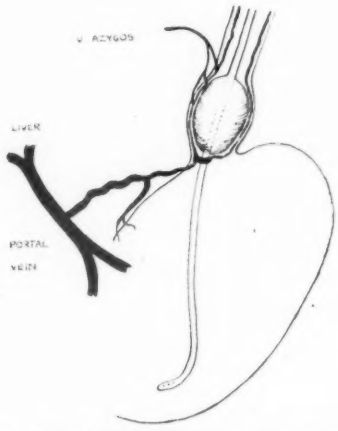

FIG. 2.—The distended balloon obstructs the collateral circulation from the gastric to the azygos veins.

œsophagus, as recommended by Rowntree (1947). However, some will bleed to death; in fact all of my cases except a few dealt with by interval surgery have eventually bled to death, and so urgent surgery may be indicated. I do not pretend to have the surgical answer to this problem, but I will show later a new emergency operation which I believe may be useful in the treatment of bleeding œsophageal or upper gastric varices.

Hiatus hernia.—Emergency surgery is not, as a rule, advisable for this condition, for the bleeding lesion is often from a peptic œsophagitis, which is unapproachable by the abdominal route.

I have never found it necessary to operate on *simple gastric neoplasm* or *gastric diverticulum* as an emergency.

Pancreatitis and carcinoma of the pancreas have both led me or one of my team to operate as an emergency, but in no case did we find that our surgery influenced the bleeding.

(2) *When is emergency surgery indicated?*—This problem naturally involves the peptic ulcer—gastritis group almost exclusively. It is certainly the most important group for it accounted for some 85% of the incidents of bleeding in my series. Opinion on when to operate is sharply divided, and will remain so because what may be the correct course for a physician in one clinic may be incorrect for one working under different circumstances or with different facilities.

Broadly speaking one of the following courses is open to the clinician.

(*a*) To treat all cases of massive gastroduodenal hæmorrhage medically, and only operate on those who seem certain to die unless surgery is invoked. This course results in late surgery on rather debilitated cases and so it *entails* a high operative mortality. On the other hand no case which would have recovered naturally will lose his life because of unnecessary surgical interference. It must also be admitted that with modern medical care and blood transfusion, some patients can be kept as a fair operative risk for several days. On the other hand some cases will die of bleeding while the physician makes up his mind and a large number of those who would have died under pure medical treatment will still die, because the surgery was late.

(*b*) The second course, and the most generally acceptable nowadays, is "selective surgical intervention", a very rational course which owes its acceptance in England in no small measure to the work and writings of Sir Gordon Gordon-Taylor. Under this regime certain criteria which are known to indicate a dangerous form of bleeding are also indications for early surgery. In particular, patients over 50 who have severe repetition of bleeding or who bleed persistently are operated upon.

(*c*) The third course is the "Finsterer" method. This policy, advocated by Finsterer

(1947), is as follows: If a patient with a history of chronic peptic ulceration is admitted with a severe hæmorrhage he is operated on at once. Finsterer argues that such early surgery carries little more risk than interval surgery, and the patient with chronic ulceration needs an operation anyhow. If, on the other hand, the patient has only a brief history or no history of ulceration, he is treated conservatively, but if bleeding is repeated or continues, exploratory operation is at once undertaken.

Now we are all aware that figures are produced which appear to prove one or the other the optimum course to follow. Obviously different types of cases, different facilities and different degrees of enthusiasm account for the varying results. In 1941 it occurred to me that if one large hospital, with a fairly uniform series of patients and facilities, were to keep careful record of each case, standardize the main treatment, but vary the extent to which surgery was employed, then some new light might be shed on the subject. Therefore with the co-operation of the physicians at St. James' Hospital, all cases of gastroduodenal bleeding were admitted to my medical or surgical gastric ward. A standardized treatment regime was laid down to eliminate as many variables as possible. The details need not concern us now (*see* Simpson-Smith Memorial Lecture, Tanner, 1949). The surgical policy was changed at certain definite times, and the results may be seen in Table II.

TABLE II.—PEPTIC ULCER AND GASTRITIS GROUPS
(748 *Incidents of Bleeding*)

		No. of cases	Over 60	Operated on	Overall mortality	Average age of patients who died
Selective surgical intervention	Period No. 1: 1941 to 1943—operation avoided as far as possible	193	33%	5%	10%	62
	Period No. 2: December 1943 to June 1944—operation earlier, always gastrectomy	60	33%	15%	20%	62
	Period No. 3: June 1944 to December 1947—operation early, simplest to stop bleeding	312	35%	11%	11%	65
	Period No. 4: January 1948 to September 1949—"Finsterer"	183	42%	60%	7%	66

In the last group we operated on 60%, that is 110 of the 183 cases. I purposely avoid putting in the operative mortality, although it was low, because I am not so much interested in the operative mortality as in seeing that the largest possible number of cases who enter bleeding leave the hospital alive. The overall mortality is more important than the operative one. The operative mortality depends so much on the type of risk accepted, and if I have too tender a regard for it, then I shall be afraid to try and save the patient almost moribund with hæmorrhage.

The table also shows that the cases were of great average age, in fact it is the oldest group of such cases ever recorded. The patients operated on varied up to the age of 81, and incidentally this patient recovered. I make a special note in the table of the average age of the patients who died, for if emergency surgery led to the loss of young patients unnecessarily, we would abandon surgery. It is evident that it does not do so, the youngest death in the latest regime being 58. Of course we used some judgment in the Finsterer regime. For example, during the last period we had 3 cases of hæmorrhage from chronic duodenal ulceration in patients under 17 years of age, and none of these was operated on as an emergency. We were justified in our decision not to operate by the lower mortality in these youthful cases. In the last 501 cases of ulcer hæmorrhage in this series, we have not lost a patient under 40 years of age. Similarly we judged occasional patients with extreme lung disease, adiposity, &c., to be a better medical than surgical risk, and discarded the Finsterer ruling for them. I have not time to go into the numerous coincidental lesions these patients suffered from, but 4 had carcinoma elsewhere, there were several cases with paralysis agitans, tabes dorsalis, hemiplegia, rheumatoid arthritis, ulcerative colitis, &c., and one case each of tetany, advanced myxœdema, severe burns, and hæmophilia. Incidentally, the hæmophiliac had a gastric ulcer and recovered first under the medical regime, but later came in during the surgical regime and had a successful gastrectomy by Mr. Desmond.

(3) *What surgical technique is appropriate for these cases?* There is no satisfactory emergency abdominal operation for the patient with bleeding œsophageal varices and I have given much thought to this subject. An operation similar to one I have used as an interval operation for the condition would probably meet the case, and I advance

it tentatively. I call it "transgastric porto-azygos disconnexion". The cause of the œsophageal and gastric varices which are the source of the hæmatemesis in portal hypertension is the collateral circulation between the portal and azygos systems of veins and the object of the operation is to interrupt it below the varices, thereby reducing the pressure in the varices from that of the portal, to that of the caval circulation (Figs. 3 and 4). Periœsophageal venous transection alone is inadequate, and impractical as an emergency proceeding. It is necessary that the emergency operation be one which can be performed by an upper abdominal incision, such as that used in exploring a case of hæmatemesis of unknown origin. Therefore I suggest (1) gastric transection and resuture to interrupt the venous circulation in the stomach (Fig. 5); (2) division of all the vasa brevia to the upper part. This entails lifting the stomach forward after transection and dividing the occasional vasa brevia which run up the posterior wall of the lesser sac from the splenic trunk; (3) division of the left gastric pedicle, carefully sparing only the left gastric artery, in order to preserve a blood supply to the cardiac end of the stomach, but of course dividing the descending branch of the left gastric artery. Thereby there is complete division between the portal and azygos circulations (Fig. 6). An additional advantage is that the left gastric artery no longer intro-

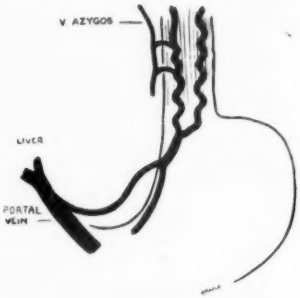

FIG. 3.—The œsophageal collateral circulation in portal hypertension.

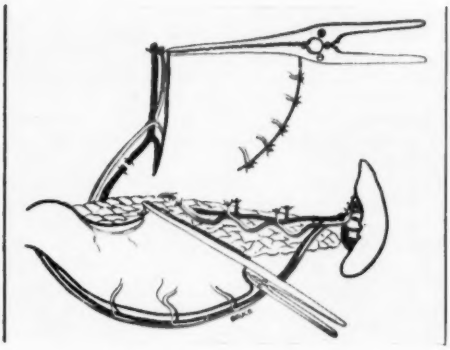

FIG. 5.—Division of splenic artery, vasa brevia and left gastric vein.

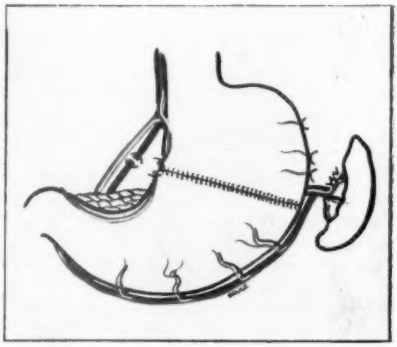

FIG. 6.—Porto-azygos disconnexion completed.

duces blood into the portal system and I have also on one occasion tied the splenic artery which reduces still further the inflow in the portal circulation. The diminution of the arterial inflow to the portal circulation thus compensates for the loss of the gastric collateral venous circulation.

How long its effect will last I do not know, for *some* fresh collaterals will eventually grow across the anastomosis. In the two cases on which I have performed this operation no ascites occurred and no recurrent bleeding thus far, but both are under a year since operation. Even if cirrhosis of the liver is found at operation careful search for an ulcer must be made, for such ulcers, in a hypertensive medium, are prone to bleed and I have three times performed gastrectomy for duodenal ulcer associated with hepatic cirrhosis.

Operations for bleeding peptic ulcer and gastritis.—Should one do the smallest operation possible, or a gastrectomy, for ulcer? If one is well acquainted with gastrectomy for ulcer, particularly for difficult duodenal ulcer, then I believe that gastrectomy is best, and that is the operation I now perform.

All cases are operated on under local anæsthesia. A few are too ill for general anæsthesia and local appears to upset them least. Its universal use also removes a variable—that of variable forms of anæsthesia—from our series.

(i) *High gastric ulcer.*—For this we perform a Pauchet modification of the Billroth I operation, removing a wedge-shaped piece of the lesser curve. The resected specimen obtained by such a procedure is well shown in Fig. 8.

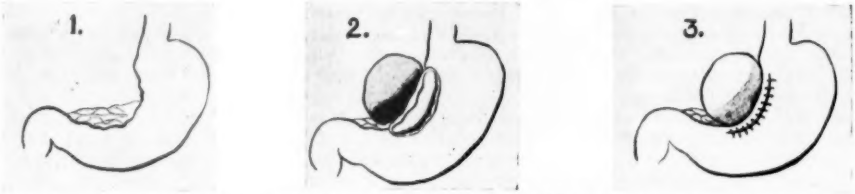

FIG. 7.—Massive gastric ulcer. The ulcer is "pinched off" and the ulcer edges trimmed and closed.

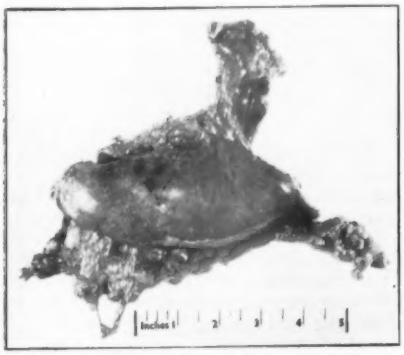

FIG. 8.—Resected stomach obtained after a Pauchet modification of Billroth I gastrectomy.

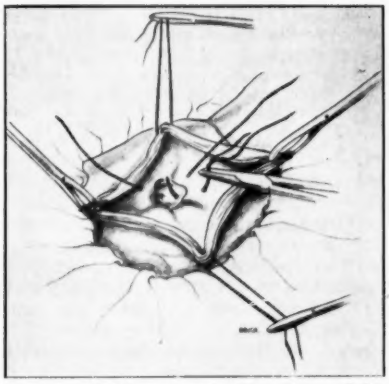

FIG. 9.—Duodenotomy. The edges of the ulcer crater are closed with deep silk sutures.

(ii) *Massive gastric ulcer in debilitated patients.*—Occasionally extremely fragile or aged patients suffer massive bleeding from a giant gastric ulcer which penetrates the liver and/or pancreas. In 3 or 4 grave cases of this type we considered that the patient might withstand minimal interference, but no gastrectomy, and the ulcer was too big to contemplate local excision. In these cases, we separated the ulcer from the liver or pancreas by "pinching off", taking great care not to damage the ulcer base (Fig. 7). The edges of the large hole left in the stomach were carefully sutured—taking care to make the sutures deep enough to get the whole of the ulcer edge. Two of the cases as a result had a stenosed stomach and gastrojejunostomy was done, but all recovered.

(iii) *Duodenal ulcer.*—For a time, during 1948, we made a longitudinal incision in the duodenum, closed the ulcer crater with deep sutures (Fig. 9), and after closing the duodenum longitudinally—to narrow it—performed a gastrojejunostomy. We had three recurrent hæmorrhages following this, one being fatal, but it undoubtedly saved lives on the whole. However, this year we have performed gastrectomy for duodenal ulcers and have no cause to regret our decision. I must emphasize that much experience of the dissection of chronic duodenal ulcer is necessary before embarking on gastrectomy for bleeding duodenal ulcer.

(iv) *Gastrojejunal ulcer.*—For this we open the stomach and occlude the bleeding point, and return later for gastrectomy, vagotomy or both. Occasionally, in a good-risk case, emergency gastrectomy is advisable.

(v) *Gastritis.*—Before deciding that bleeding is gastritic in origin, the most careful palpation and inspection of all parts of the stomach are necessary. The site of ulceration may merely show a blush, or local vascularization, or a little fixity of the serosa on the muscularis. On palpation the ulcer may not be felt and sometimes the sclerotic vessel in the crater is felt before the crater itself. I used to tie the right and left gastric, and right and left gastro-epiploic vessels, if at laparotomy no ulcer or other cause of bleeding was found, and yet massive hæmatemesis had occurred. In nearly every case this succeeded, but in a recent case of erosive gastritis in a youth aged 26 it failed. In his case, after he had had thirty-three pints of blood, on the tenth day, we had to operate a second time and perform a gastrectomy; this was followed by recovery. This case persuades me that if bleeding is of really great severity, and no lesion is found, then gastrectomy is advisable, for it removes four-fifths of the erosive area and partially devascularizes the remnant. If bleeding is only moderate, then I would still merely ligate the four main gastric vessels.

There are three further points. The surgical series requires that an experienced surgeon be continuously available. A good deal of the surgery has been done by my Assistant, Mr. A. M. Desmond, and some cases by my registrars, Messrs. W. W. Davey, C. M. Craig, and P. B. Counsell. Although of course the surgical regime requires vigilance it is not so anxious, nor does it involve so much nursing as the medical regimes. Great enthusiasm is required for good results by either method. Secondly I do not consider that we have in any way solved our problem. I have proved that our results have improved since we undertook much more frequent surgery for hæmatemesis and melæna. To see if this is accidental we intend to revert for a period to selective surgical intervention, in order to study the result of the change back. There is, however, one great advantage in this frequent surgery. When we discharge patients on whom we have performed a gastrectomy for hæmatemesis, most of them are rid of their ulcer trouble for ever. When we discharge them after conservative treatment, we know that many will return with bleeding, and some will die of it.

Mr. Ivor Lewis: Patients with hæmatemesis should be admitted to the medical wards and the ideal combination is a keen young physician and a somewhat reluctant surgeon.

What we require in the management of hæmatemesis is a differential *prognosis*—to pick out certain groups where medical mortality is specially high. This has not yet been achieved. My own rough guide is that operation should be considered in all patients over 40 with a hæmoglobin under 40%, particularly if the hæmorrhage recurs, or there has been persistent pain. Avery Jones has shown that patients with hæmatemesis from duodenal ulcers and chronic gastric ulcers, if they are over 50 and have a sharp recurrent hæmorrhage, are more likely to die than to recover in spite of transfusion and the best medical treatment. As for the group under 40 it must be accepted that the hazard of an emergency operation is likely to be higher even in the best hands than the low 2 to 3% of good medical treatment. This does not mean that the physician or the surgeon should adopt a wooden attitude just because the patient is young; to relate that a patient bled so copiously and repeatedly as to need 20 pints of blood is more of a tribute to the patient's fortitude than to the doctor's good sense.

At the North Middlesex Hospital we admit about 120 cases of hæmatemesis and melæna per annum. Seldom a year passed without one or two young men of 30 being among the deaths and we would now consider operating even in these younger patients, when they have already had, say, 10 pints of blood.

Is it acute or chronic? Duodenal or gastric? I have operated in over 50 cases of hæmatemesis and have, for my own edification, compared our pre-operative diagnosis with the operative findings. Whether duodenal or gastric?—correct in 60% of cases. Whether acute or chronic?—correct in 60% of cases also. In other words, apart from cases with an X-ray which is both positive and recent, the opinion is little better than tossing a coin. This shows that the old injunction that you should only operate "where it is known that the patient has a chronic ulcer" is not very valuable except for the small number who have recently been X-rayed. Similarly the tag about the patient who is arteriosclerotic is not very important—the only artery that matters is the *open* one, and this is always sclerotic in the base of a chronic ulcer.

When to operate? The surgeon would like to operate as soon as the hæmorrhage recurs and before the patient collapses again. The houseman is usually phoned to "come at once as the patient has just vomited 2 pints of blood and is cold and clammy". It is not generally appreciated that the actual hæmorrhage precedes the summons by perhaps an hour or two. It is the *vomiting* with its commotion and straining which seems to precipitate the collapse.

I have found it a useful practice when on the look-out for a critical relapsing hæmorrhage to leave a Ryle's tube in the stomach (to the 2 rings) and have the nurse take a sample every half-hour. This simple measure will give the signal long before any sign. During the period of watching there is one very important thing to do. That is to transfuse the patient slowly if his hæmoglobin is under 40%. And there is one other thing still more important in my opinion: *not* to transfuse him if his hæmoglobin is over 50%. The blood should be held in reserve; if the hæmorrhage does not recur he will not need it; if it does, he will need it all, before, during and after the operation.

Preparation for operation.—The surgeon should have nothing to do with the physician who calls him only as "a last desperate resort", with the patient cold, pulseless and uræmic. In reasonable cases after a sharp hæmorrhage it may take anything from two to twelve hours to make the patient fit for operation. It is wrong to think that this process can be indefinitely hurried by giving the patient still more blood, more rapidly—a common error. A circulation which has been depleted for some time should be restored quickly, but not at one fell swoop. Only in rare exceptions should blood be given faster than about a pint an hour, even pre-operatively. Very few of my patients have had more than 5 pints of blood from the moment operation was decided on—perhaps 2 before, 2 or 1 during, and 1 or 2 after, the operation. There are two provisos regarding the surgeon who undertakes these cases: (*a*) he must be able to do an ordinary gastrectomy soundly and well in little over the hour, and (*b*) he must be prepared to deal with these cases any time of the day or night. Most of mine have been done between midnight and 3 a.m.

What to do (*a*) *when you find the lesion;* (*b*) *when you cannot find the lesion.* (*a*) In my opinion the minimum requirement in dealing with a bleeding artery in a peptic ulcer is (1) to ligate the vessel, and (2) to exclude it from subsequent contact with gastric juice. It must therefore not be thought that operating on hæmatemesis is synonymous with gastrectomy, a point so insisted on by Sir Gordon Gordon-Taylor. My practice is as follows:

In chronic gastric ulcer: gastrectomy with removal of the ulcer. (But if the ulcer is large and penetrating, its base is left in situ, and the artery under-run proximally and distally.)

In chronic duodenal ulcer; ligating the artery (gastroduodenal usually) both sides, plus gastrectomy or at least exclusion.

In subacute or acute gastric ulcer: elliptical resection of the ulcer.

(*b*) What does one do where one cannot find a lesion by sight or feel? Either (1) close the belly, or (2) open the stomach and find the vessel. Usually I find it more satisfactory to do the latter, having gone so far. It is a comfort to know the transfusion will stay put. Only in one case has the lesion not been apparent. The mortality for the cases operated on for bleeding peptic ulcer has been 15%. Looking back I consider several of the deaths should have been avoided. 15% is a high mortality for gastrectomy—about five times more than for "cold" gastrectomy. But the mortality for this group of cases, without operation, is over 50%.

Finally I would recall the simple fact that what these patients are suffering from is a *secondary* hæmorrhage, and that the bleeding artery is often as large as the radial.

Mr. A. M. Desmond: In presenting my personal operative results it should be emphasized that I was but one unit in a co-ordinated team under Mr. Norman Tanner especially trained to deal with gastroduodenal hæmorrhage.

My results in 53 cases are shown in Table I:

TABLE I

Cause	No.	Gastrectomy	Simple procedure	Deaths	Remarks
Gastric ulcer	26	22	4	2	1 death followed simple procedure 1 followed gastrectomy
Duodenal ulcer ..	16	16	—	—	—
Stomal ulcer	1	—	1	—	Bled post-operatively. Subsequent vagotomy
Erosive gastritis ..	2	1	1	—	Proven cases
No abnormality found	4	—	4	—	G.U. discovered later, by gastroscopy in one
Carcinoma of pancreas	1	—	1	1	Ligature of gastroduodenal artery and gastro-enterostomy performed. Hæmorrhage not controlled
Portal hypertension ..	1	—	—	1	Ligature of coronary vein. Bleeding not controlled
Uræmia	1	—	1	1	Bilateral pyonephrosis
Carcinoma of stomach	1	—	—	1	Abdominal total gastrectomy

Some of these cases were operated upon before 1948 under the principle of selective surgical intervention. Others, in the last two years, were treated according to the principles of Finsterer.

In 4 cases, no lesion was found at operation and vasoligation was performed. In one a gastric scar was revealed on subsequent gastroscopy. An abdominal total gastrectomy was performed for hæmorrhage from a leather-bottle stomach with fatal result.

Carcinoma of the pancreas as a cause of hæmatemesis is not well recognized. We have experienced two cases. In my case the tumour had ulcerated the duodenum, and in spite of a gastrojejunostomy and ligation of the gastroduodenal artery the patient bled to death. In the other case, the tumour had involved the posterior gastric wall.

The deaths in the gastric ulcer group:

Case I.—At operation a large pyloric ulcer was freed from the liver and the stomach sutured. Obliteration of the lesser sac was noted.

4th day: He vomited blood.

6th day: He developed intestinal obstruction due to old adhesions and succumbed after further aparotomy.

P.M.—There was a giant gastric ulcer with erosion of the splenic artery. This ulcer had not been demonstrated at operation (Fig. 1).

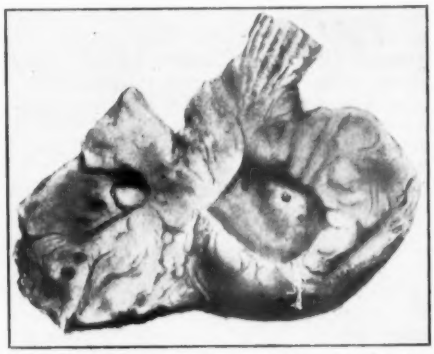

FIG. 1.—Autopsy specimen of stomach showing giant gastric ulcer eroding the splenic artery.

Case II.—Admitted to general medical ward as carcinoma of lung. Found to be having melæna stools and on questioning admitted to constant melæna for one week. Suffered from severe chronic bronchitis and emphysema.

At operation multiple small subacute gastric ulcers. Gastrectomy performed.

Died from bilateral bronchopneumonia on 12th post-operative day.

Inspired by Sir Gordon Gordon-Taylor, the most favoured method of treatment in this country has been by selective surgical intervention.

After studying our own case histories I would like to emphasize the importance of pain in influencing the decision to operate. The following would suggest that surgery should be considered: (1) A particularly severe bout of pain immediately preceding the hæmorrhage especially if associated with vomiting. (2) Radiation of pain to the back between the "shoulder blades" or to the shoulder tip. (3) Persistence of pain after the hæmorrhage.

In most cases the pain disappears almost as soon as the hæmorrhage occurs. Sometimes it does not do so, or the relief is but temporary and pain recurs soon afterwards.

Another highly dangerous type of case is the one who, whilst in hospital under treatment for ulcer, suffers a severe hæmorrhage. The reason for these seems to be associated with the activity of the ulcer. There is a type of ulcer in which spreading necrosis of the gastric or duodenal wall occurs, and these ulcers may perforate or rapidly erode a large vessel.

Two examples of such ulcers occurred in this series:

A man aged 35 came to the clinic with a two-months' history of vague dyspepsia, but with some pain in his back. A barium meal was taken but before it was seen he was admitted with a perforated gastric ulcer which was sutured.

Five days later he commenced having large hæmatemeses which failed to respond to conservative measures.

On the 6th day the abdomen was re-opened and an enormous saddle ulcer was freed from the pancreas and the stomach sutured. He did well, and as a gastroscopy performed six weeks later showed a large ulcer still present, a gastrectomy was performed.

A man aged 66 was operated on for a perforated gastric ulcer. The ulcer was small and on the anterior wall of the lesser curve.

Post-operative urinary retention necessitated a cystotomy. On the twelfth day he had a severe hæmatemesis and melæna.

Conservative treatment was considered advisable, but in spite of repeated transfusions, melæna continued on and off.

On the 37th and 38th days he suffered severe collapses with melæna. On the 40th day the abdomen was re-opened. Practically the whole posterior gastric wall was replaced by an ulcer penetrating the posterior abdominal wall. It was freed and the stomach sutured and a drainage tube inserted. A gastric fistula developed and a feeding jejunostomy was formed. The fistula healed on the 1 th day and he recovered well. Prostatectomy was later performed by Mr. H. K. Vernon and he remains in excellent health.

A high blood urea is a grave prognostic sign but we feel that it should not constitute a deterrent to surgery. We have successfully operated on 8 cases with values over 120 mg.%, three cases having values over 150. We feel that a patient with severe azotæmia is better able to tolerate a surgical operation under local anæsthetic than he is a further severe hæmorrhage.

With increasing numbers of operated cases there has naturally been an increase in diagnostic errors, although the percentage is roughly unaltered. In an attempt to obviate these errors we have resorted to emergency gastroscopy and not only have we clarified the situation in many cases, but have so far encountered no untoward results. The discovery of an ulcer does not necessarily mean an emergency gastric resection is performed. If a large ulcer with a sealed vessel is seen, however, we would operate within twenty-four hours.

As soon as the decision to operate has been made the patient should be brought as quickly as possible to the best possible state to withstand operation. Three points must be emphasized:

(1) The patient's condition may improve so dramatically that one may be sorely tempted to postpone operation. This would be ill-advised as the rapid increase in blood pressure may precipitate a further hæmorrhage.

(2) Resuscitation must not be too vigorous as a further hæmorrhage may occur before the patient has reached the operating theatre.

(3) It would be better if facilities permit to carry out the final resuscitation in the operating theatre or anæsthetizing room.

Dr. F. Avery Jones: From a personal experience of over 400 cases of frank hæmatemesis and melæna treated before 1945, I became convinced that there was scope for surgery in the management of this emergency. The cases which carried a particularly high mortality were those over middle age, who had a probable chronic ulcer, and who bled again after admission to hospital. Some of these cases had other serious medical complications which would preclude surgery but there was a small residue of cases where emergency surgery might have been successful. Since 1945, emergency partial gastrectomy has been performed in patients falling within this category and so far 23 cases have been operated on with 4 deaths. The expected mortality under medical treatment would have been at least 12 and probably more. The ages of these cases are set out in the following table.

TABLE I

	Emergency partial gastrectomy				Laparotomy			
	Cases	(Ages)	Died	(Ages)	Cases	(Ages)	Died	
1945	3	(51, 57, 65)	—		1945	3	(17, 41, 47)	—
1946	2	(54, 66)	—		Part 1949	3	(35, 47, 64)	—
1947	7	(56, 56, 59, 62, 66, 70, 75)	2	(62, 75)				
1948	6	(46, 48, 51, 57, 61, 62)	—					
	18		2					
Part 1949	5	(19, 70, 70, 68, 73)	2	(70, 68)				

It might have been thought that successful surgery which reduced the expected number of deaths on past experience would have reduced the overall mortality since 1945, but the following table shows that the mortality has, in fact, not been reduced. The explanation for this lies in the higher proportion of admissions of patients over 70. Over this age, the

mortality becomes very much increased. Under the age of 70, mortality has actually declined in recent years.

TABLE II

	Hæmatemeses		Peptic ulcer group	
	Admitted	Deaths		Deaths under 70 years of age
1940	58	5		4 in 53
1941	58	5	= 7%	5 in 131 = 7%
1942	82	5		4
1943	102	4	= 6·5%	3 in 194 = 5%
1944	113	10		7
1945	135	9	= 8%	6 in 216 = 5%
1946	120	12		5
1947	101	8	= 8%	2 in 180 = 4%
1948	122	10		5
	891	68		41 in 774
1949 Part ..	106	8		0

TABLE III

	Aged 70 and over		
	Admitted—% of total admissions		Deaths
1940	5		1
1941	3	6·5%	–
1942	6		1
1943	9	10%	1
1944	12		3
1945	13	15¼%	3
1946	26		7
1947	25	19%	6
1948	18		5
	117		27
1949 Part	23 (22% approx.)		8

It is likely that the maximum benefit from partial gastrectomy for bleeding peptic ulcer will be between the ages of 45 and 70. Over 70 there are so often serious associated medical conditions which militate against successful surgery.

Section of Laryngology

President—R. D. OWEN, B.Sc., F.R.C.S.

[*November* 4, 1949]

The Problem of Hypopharyngeal Carcinoma. [*Abridged*]

PRESIDENT'S ADDRESS

By R. D. OWEN, B.Sc., F.R.C.S.

THE anatomists label all structures from the level of the soft palate to the pharyngo-œsophageal junction as "pharynx"; but I like the old terminology of "hypopharynx", by which I mean the pyriform fossæ and postcricoid space, down to the entrance of the œsophagus.

I do not propose to discuss carcinomatous lesions involving the epiglottis, aryepiglottic folds, and the lateral wall of the pharynx above the laryngeal opening.

In a discussion in this Section on malignant disease of the pharynx (Simpson *et al.*, 1948) it was shown that cancer of the lower pharynx still remained a difficult proposition. Negus (1948) states regarding prognosis, that extrinsic cancer is amenable to extensive operation in a limited number of cases only, and rarely with a permanently successful result. Irradiation offers no better prospects.

The choice of treatment is not easy to decide upon. When we are confronted by an early operable case there is a tendency to take the path of least resistance and hand over the patient to the radiotherapist. Irradiation has been and is being tried in various forms, but still with limited success. It makes one wonder what constitutes the greater form of misery—to die with no attempt having been made to cure with radical surgery; the suffering that comes with the recurrence after radiotherapy; or the lot of a patient who has had a pharyngo-laryngectomy performed, and the suffering that follows when a recurrence appears, particularly before the plastic phase has been completed. The uncontrolled dribbling of saliva, and being without a voice to express one's misery, still remain a grim and sad picture.

Our sincere hope is that improvement in radiotherapeutic methods may one day reach the stage when pharyngeal cancer can be treated with greater confidence, and even make us forget about the necessity for radical surgery.

The history of the patient must be carefully taken and the significance of symptoms described as "catch in the throat" or "pricking sensations" must be appreciated.

This symptom of "pricking sensation" can be very confusing, as a common cause of discomfort in the throat is the retention of debris or pus, or even small calcareous deposits in the tonsillar crypts. It is very easy to clean out and empty the crypts, and then follow this by using the laryngeal mirror to examine the lower pharynx and the larynx. Having found a normal larynx and clear pyriform fossæ, without the retention of mucus in them, one may conclude that the cryptic activity in the tonsils is the cause of the pricking sensation.

Tonsils have been removed as being the cause of this discomfort, and within three months I have seen the patient referred because of dysphagia and glands in the neck, due to a postcricoid growth which was undoubtedly present at the time of the removal of the tonsils.

When the patient's throat symptoms are combined with voice changes, such as a moist, muffled tone, or huskiness, one immediately becomes suspicious of a laryngeal or a pyriform fossa lesion. Voice change, with a postcricoid growth, is, however, a late symptom. Yet it is sometimes amazing what an enormous mass can be present behind the cricoid with very little voice change, and even without the fixation of a vocal cord.

It is also true that dysphagia need not be very pronounced when the lesion is localized to the posterior or anterior wall of the hypopharynx, but when the spread is tending to become annular, then real dysphagia appears, with the usual squelching noise and a slight cough when attempting to drink fluids.

There are recorded cases of congenital narrowing of the upper gullet, without the history of dysphagia. Brown Kelly once showed a post-mortem specimen of a man of 35 who never complained of trouble in swallowing, and yet the lumen of the pharyngo-œsophageal junction had a diameter of only 4 mm. Chevalier Jackson made the observation that well-masticated food can pass through a lumen of 5 mm., and that a malignant stricture of a 3 mm. lumen will take food ordinarily eaten by the average man, provided it has been put through a sieve of 25 meshes to the inch.

It is little wonder that the general practitioner, when confronted by a dysphagic patient, can be misled.

It means also that indirect laryngoscopy is not always enough. The hypopharyngeal speculum, or the œsophagoscope, ought to be used when there is a doubt about the character of the pain or discomfort. This is the only way to try and establish an early diagnosis.

It is true that operation, in properly selected cases, is justified by results. As John Simpson said, the figures published by the late Mr. Colledge in 1943 still remain the peak to which this branch of surgery has been brought: That 13 out of 39 patients, i.e. 33%, were well, ten years after lateral pharyngotomy, and that out of 16 cases of pharyngo-laryngectomy, 6 (or 37%) were alive and well.

The radiotherapist cannot as yet produce figures comparable to those published by Colledge. Radiotherapy for cancer of the pyriform fossa, the postcricoid area, and the cervical portion of the œsophagus still proves to be disappointing though fairly good results are obtained in the vallecular regions, epiglottis, and the aryepiglottic folds, but not in the hypopharynx proper. That is why we have to continue to think in terms of radical surgery. The classification of neoplasms in this area is important, with an accurate picture of the localization and extent of the growth.

These essentials were discussed at a memorable meeting of this Section in December 1931 (*Proc. R. Soc. Med.*, **25**, 431).

The merits of plain excision on the one hand, and radium combined with surgery on the other, were discussed. That is nearly nineteen years ago, and as far as I can see, the problem remains the same to-day.

To-day we are of the opinion that under certain conditions the loss of the larynx is relatively of minor importance in a life-saving undertaking. The ideal, however, is to try and make certain that cases are brought to one's notice early enough to avoid the necessity of mutilating operations. We still have to admit that the net survival rate, even for treatable cases, is disappointing, and that the proportion of late cases coming for treatment is far too high.

What, then, are the difficulties that continue to make this hypopharyngeal problem so elusive? I believe that up to now we lack the courage of conviction. We refuse to recognize the fact that certain early signs and symptoms belong to a phase that ought to be regarded as precancerous. I know that the word "precancerous", in the pathological hierarchy, is not altogether popular, but there is no reason why the word should not be used, provided one knows its meaning. According to Professor Scarff it should be used to denote any condition of the tissue in which malignancy is more likely to occur than in normal tissue.

In a discussion that took place in this Section in February 1936 (*Proc. R. Soc. Med.*, **29**, 526), Mr. Negus described two cases of chronic hypopharyngitis that eventually developed postcricoid carcinoma. He went so far as to say that the right course was to excise that segment of the œsophagus before carcinoma developed.

Even in 1931 Mr. Negus emphasized the need of early diagnosis, and supported this teaching by mentioning the case of a patient with pain on swallowing, which was referred to the pyriform fossa. Direct examination showed raised small masses on the lateral wall of the pyriform fossa. Microscopical examination showed this to be a fibroma, with inflammatory infiltration. Mr. Negus performed a transthyroid pharyngotomy, which was a complete success. He made it clear that there were no malignant changes on examination of the specimen, but still he regarded it as precancerous.

That to me is the courage of conviction. In other words, whenever one is certain that a condition of hypopharyngitis is progressive, everything else being equal, it is one's duty to regard it as precancerous.

While dwelling on this precancerous problem, I shall refer to the Paterson-Brown Kelly syndrome—sometimes incorrectly described as the Plummer-Vinson syndrome. Paterson, in 1919, was the first to draw attention to the fact that the development of a postcricoid carcinoma, in women complaining of this syndrome, was far too frequent an occurrence to be a mere coincidence. Brown Kelly, in his Semon Lecture in 1926 said: "I think that the relation of pharyngo-œsophageal spasm to anæmia would be a fruitful subject for investigation, particularly when we consider some of the complications such as postcricoid carcinoma."

In 1939 R. R. Simpson, of Hull, stated that examination of the records of his cases suffering from this syndrome, where œsophagoscopy was carried out for dysphagia, revealed that at least 50% either had, or developed, a carcinoma. His figures, however, showed that the lower end of the œsophagus was more vulnerable than the postcricoid area. 10 out of 18 cases developed malignant disease; 4 postcricoid, 5 the lower end, and 1 the lower third—all of them complaining of simple achlorhydric anæmia and a long-standing "small swallow".

I cannot say that in my experience of the Paterson-Brown Kelly syndrome has the incidence of carcinoma as a complication been so high.

Ahlbom of Sweden, in his long series, appeared to have no difficulty in associating a proportion of carcinoma of the mouth, the pharynx and the œsophagus with the Paterson-

Brown Kelly syndrome, but no figures regarding the postcricoid lesion have been mentioned. Since then, Flett of Derby has stated that out of 100 cases which he followed up complaining of this syndrome, not one developed a carcinoma, but after communicating with him later I know that he has altered his opinion since then. Colledge, in his Lettsomian Lectures, mentions a case of a female with the Paterson syndrome and a postcricoid carcinoma, on whom he had performed a pharyngo-laryngectomy for the removal of the growth. This patient, ten years later, came under observation (at the Cardiff Royal Infirmary) with a carcinoma of the lower end of the œsophagus and the cardiac end of the stomach.

In August of this year I followed up the subsequent history of 34 female patients who had been in-patients at the Cardiff Royal Infirmary for investigation of the syndrome of dysphagia with anæmia. These patients had been admitted during the years 1934–35, and I am excluding all those who appeared during those years for the first time with a postcricoid carcinoma. I chose the years 1934–35 as we happen to have had an exceptional number of these cases during those two years. Also, now that fifteen years have elapsed it gives, in my opinion, a fair period to enable one to assess the course of events.

R. R. Simpson in 1939 said: "The few writers on this subject referred to the supervention of malignant disease as a possibility, but so far no attempt has been made to assess the frequency of this occurrence, despite its general recognition."

Of the 34 female cases that came under my care, all had direct œsophagoscopy performed on them, as well as the usual blood counts, and some had fractional test meals. They were diagnosed as cases of dysphagia with simple hypochromic anæmia. Direct examinations were carried out in order to dilate the cricopharyngeus web, to improve the swallowing, and in particular to try and assess correctly the mucosal changes.

The follow-up of these cases after fifteen years showed:

TABLE I

No. of cases seen during 1934–35	34
No. still surviving without any evidence of malignant disease	23
No. that developed a postcricoid carcinoma	5
No. not traced after 1939, but free from malignant disease up till then ..	6

I was surprised to see that so many of these women remained free from malignant disease. My impression had been that cancer occurred more frequently, but not in the high percentage mentioned by R. R. Simpson.

Of the five that developed a postcricoid carcinoma, Table II shows the varying periods at which this developed after direct œsophagoscopies, and this enables one to focus attention on the possibility of a precancerous condition in this syndrome.

TABLE II

Patient	No. of dilatations (direct œsophagoscopy)	Postcricoid growth developed	Age when developed
1	3 (1934, 1938, 1940)	1947	75
1	2 (1934, 1935)	1938	55
1	2 (1934, 1936)	1937	63
1	1 1935	1937	39
1	1 1934	1942	42

Out of the 23 classified as having no malignant disease, 12 of these women reported having had considerable benefit after dilatation. They swallowed solids easily for about twelve months to two years; after that symptoms gradually reappeared. They returned to a diet of soft food and liquids and any attempt at solids produced a choking attack. The following letter is typical of others sent to me from these patients during the course of the follow-up: "I received treatment at your Hospital in 1935 and 1945. After both occasions I enjoyed a period of two years of perfect swallowing but now the condition has gradually returned and I cannot go without the fear of choking during a meal when trying to swallow solids." 11, however, said that they are very much better and able to eat everything with reasonable care.

Their own doctors followed up the treatment of the hypochromic anæmia very conscientiously in the majority of cases, and I daresay that this, as well as the dilatation, has helped to bring about an improvement in so many.

But what about the 12 that continue to complain of the dysphagic symptoms? Is it the right treatment to encourage these women to come up for repeated dilatation? I have already mentioned that three direct œsophagoscopies during a period of six years made no difference to one patient, and did not prevent the appearance of a postcricoid growth thirteen years after the first dilatation. Would more frequent dilatations have succeeded in preventing malignant changes? At the same time the fact that 11 out of 23 are more or less symptom-free after one dilatation makes one hesitate in being dogmatic about the fact that hypopharyngitis is to be regarded as precancerous.

The question is whether these 12, whose ages average 64, are becoming more vulnerable to the development of hypopharyngeal cancer, or even the localization of cancer lower down in the œsophagus and why should the dysphagic symptoms reappear?

The results of the follow-up inquiry of these 34 females who were seen first in 1934/35 may be interpreted as follows: At the end of fifteen years, the proportion who had developed postcricoid carcinoma lies somewhere between 15 and 32%, assuming that the six who were not traced after 1939 can be regarded as free from cancer.

We know of no figures showing the incidence of the disease in the general population, but Stocks has shown (Statistical Review, part 3, text, 1940–45, Table LXXX) that the mortality rate from cancer of the pharynx in females since 1911 has not been greater than 25 per million at any age-group. 15 to 32% seems therefore a very high figure, and certainly suggests some extra risk of incurring the disease amongst people with dysphagia and simple hypochromic anæmia.

Mean ages of the groups are perhaps not the best approach to the study of the effect of age on prognosis, and in any case they should all be measured from the same point of time. One would like to measure them from the age at which the so-called "precancerous" state developed, but we do not know this, and the nearest approximation we can get to it is the age at which patients were first seen and dilatation was performed.

In the following table the three categories have been classified in 10-year age-groups, according to their age in 1934–35, when first seen.

TABLE III.—AGE DISTRIBUTION OF PATIENTS ACCORDING TO THEIR AGE IN 1934–35 WHEN FIRST SEEN

		Ages 30–	40–	50–	60–	Total
A.	With symptoms but no growth	4	3	4	1	12
B.	Without symptoms	2	8	1	–	11
C.	Developed growth	2	–	1	2	5
	Total	8	11	6	3	28
C.	as percentage of total.. ..	25%	—	16%	66%	

The figures are too small to draw any valid statistical deductions—the difference could have arisen by pure chance—but if the percentages should remain the same on a larger set of figures, or if the analysis was repeated on several series of patients with similar results, then it would be suggestive that it is after the age of 60 that the risk of growth developing becomes greatest.

In the present age distribution of Groups A and B, 50% of the 12 women with symptoms but no growth are now, in 1949, over 60, as compared with 64% of the 11 women who are free from symptoms. The actual age distributions are shown in Table IV and it will be interesting to follow the subsequent history of the two groups.

TABLE IV.—AGE DISTRIBUTION IN 1949 OF GROUPS A AND B

	Age 40–	50–	60–
A ..	2 (16·7%)	4 (33·3%)	6 (50·0%)
B ..	1 (9·1%)	3 (27·3%)	7 (63·6%)

My clinical conclusion is that 12 women whose ages average 64, and have complained of dysphagia for at least fifteen years, so far show no sign of malignant disease. 11 responded to treatment and are more or less symptom free. 5 developed postcricoid carcinoma; 3 after more than one dilatation. It is important to remember the insidious onset of cancer. These women, through the years, have schooled themselves to put up with this persistent, painless pushing down of food. Some become so accustomed to it that they regard it as normal. Then sudden serious attention may be drawn to it by some mischance when a bolus of food sticks in the upper food passage. A direct examination may be carried out with a view to dilatation and to assess the condition of the mucosal lay-out. At the same time a piece of mucosa may be taken for microscopical section and, more often than not, a report is returned,

showing that the appearance is not suggestive of neoplasm but more like inflammatory granulation tissue.

For years one can watch patients with this kind of history and the majority seem to go on without developing the complete picture of malignant disease—but they must be regarded as vulnerable and followed up if proper and early diagnosis is to be made.

Early diagnosis of carcinoma of the postcricoid space and the upper end of the œsophagus means the avoidance of the major and mutilating operation of pharyngo-laryngectomy.

If the mortality rate in this disease is to be reduced, the recognition of signs and symptoms suggestive of a precancerous condition are important, but I shudder to suggest that *all* these patients should be operated on during that phase, apart from having direct œsophagoscopy performed.

The series of malignant tumours that I have removed from the hypopharynx show certain variations in the clinical pictures. There is a marked clinical difference between the soft, spreading, ulcerative type (Fig. 1), which generally involves the postcricoid space and the upper end of the œsophagus, and what one may call the hard, scirrhous, infiltrating variety. With the former, secondary infection colours up the picture and metastases are more frequent, whereas with the latter, active ulceration is less of a feature, as is secondary infection, and secondary glands are not so frequent. Fig. 2 illustrates the endoscopic appearance of the soft ulcerative type. It is to be seen mostly in females who have had a postcricoid web for years. As already stated a number seem to improve after dilatation. Some, however, turn up two or three years later with a foul-smelling ulcerating mass involving the pyriform fossæ and both the anterior and posterior walls of the hypopharynx. The cords may be fixed and there may be further extension of the growth to involve the soft tissues of the neck, such as the thyroid gland, as well as secondary glands.

FIG. 1.

FIG. 2.—Endoscopic view of the "soft ulcerating type".

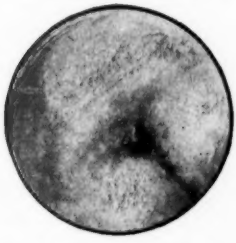

FIG. 3.—Endoscopic view of the hard rigid walls with a narrow lumen at cricopharyngeus level.

The other clinical endoscopic picture to be seen is the type where a direct œsophagoscopy has had to be repeated three or four times, and where, at the first dilatation, the so-called membranous web is not encountered. In these cases, even after four dilatations, improvement is not maintained. Instead of a web one meets a rigidity and firmness surrounding the whole of the hypopharyngeal wall as illustrated in Fig. 3. One may not see any mucosal changes, but if handled roughly there is a tendency to bleed.

Here the stenosis may be due to submucosal fibrosis. The anæmic picture associated with web formation is not always present and makes one conclude that this is another distinct

clinical type of postcricoid narrowing. It differs entirely from the "web" formation of the Paterson-Brown Kelly syndrome.

As an example of what I regard as the persistent or progressive fibrotic type, without malignant changes, I am reminded of a woman, aged 64, who was admitted as an emergency with a history of dysphagia for at least thirty years. Ten days before admission she found herself unable to swallow anything solid, and even fluids gave her the greatest difficulty.

On admission she was extremely dehydrated, frail and wasted. She looked anæmic, but the tongue did not show the usual glazed atrophic appearance, and the nails were not spoon-shaped. Indirect laryngoscopy showed nothing, apart from the retention of mucus in the pyriform fossæ. A direct œsophagoscopy showed marked rigidity and thickening of the hypopharyngeal wall, commencing about 2 cm. below the level of the arytenoids. The picture gave the impression of a circular stricture. In the very narrow lumen was found impacted a small foreign body, and this was removed without difficulty. Within a few months the same accident happened again from which she did not recover.

Post-mortem examination showed that there were two constricted areas, the centres being 3·5 cm. and 9 cm. respectively, below the laryngeal opening, the upper one being by far the most marked. To the naked eye the mucosa in the pyriform fossæ appeared normal, but in the postcricoid region it looked opaque and thickened. This latter appearance extended in a marked degree for about 12 cm., the rest of the œsophagus being normal. Histologically, at the site of the stricture there was marked infiltration with inflammatory cells, principally lymphocytes and plasma cells, but also a few polymorphonuclears.

The microscopical section, Fig. 4, showed that at one place the inflammation extended through the muscular coat, completely destroying the latter. Nearby, where the lesion was less severe, the muscle fibres were thin and there was fibrosis and inflammatory infiltration.

FIG. 4.—Low power.

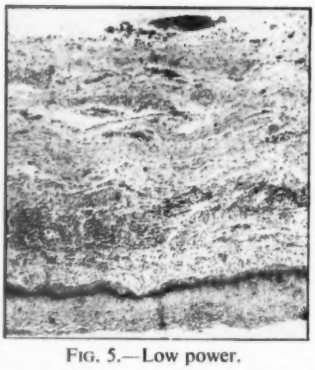

FIG. 5.—Low power.

Another section, Fig. 5, showed the part below the upper stricture, where the inflammatory infiltrations were more confined to the submucosa, and the muscle layer showing little infiltration and less atrophy.

In extent the fibrotic infiltration involved at least 9 cm. of the hypopharynx and the upper œsophagus, with the main stricture 3·5 cm. below the laryngeal opening. I feel it fair to assume that the whole of this segment must be regarded as more vulnerable than the rest of the œsophagus, and that had she lived, other changes such as malignancy might have supervened at any level within the 9 cm. There is no doubt that continued trauma to this inflamed mucosal surface, plus the unhappy fibrotic bed on which it lies, are factors that cannot be ignored in regarding this segment as precancerous.

In view of these clinical pictures that I have mentioned I would like to discuss the types of tumours operated on.

The soft ulcerating type when it involves the whole of the lumen and is not confined to the postcricoid plate is, as far as my experience goes, the most difficult to cure surgically. The presence of glands, however early, makes the prognosis much worse. Even after a very sweeping pharyngo-laryngectomy, and with the absence of secondary glands at the time of operation, recurrence may take place sooner or later. This happens either lower down in the œsophageal stoma or with secondary glands elsewhere. Even when a cut margin of an inch

has been allowed below the level of the growth, recurrence has taken place at the cut margin. This takes one's mind back to the possibility of segmental vulnerability due to chronic inflammatory infiltration of the œsophageal submucosa as shown in Fig. 5; in other words chronic hypopharyngitis.

A lateral pharyngotomy should never be performed on the soft ulcerative type, even if considered operable and localized to the postcricoid plate. A pharyngo-laryngectomy gives a better chance of a cure.

As for the hard infiltrating scirrhous variety, as shown in Fig. 6, here the thickening of the

FIG. 6.

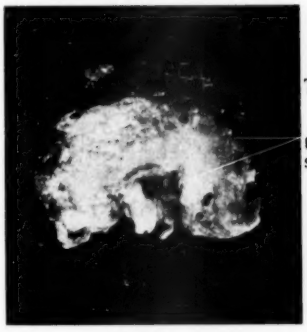

FIG. 7.

FIG. 8. × 60

œsophageal wall reduces the lumen to 2 or 3 mm. There is very little superficial ulceration and when the same segment is cut transversely, the submucous thickness of the wall compared with the degree of ulceration is seen (Fig. 7).

The tendency, when treatment is considered for these cases, is to advise removal by performing a transthyroid pharyngotomy, and in the majority there is no difficulty in peeling off the lower pharynx from the back of the larynx. When the whole segment is sectioned microscopically, one too often sees that only a small rim of healthy tissue remains beyond the limit of the neoplastic infiltration—far too small a margin for real safety (Fig. 8). This section illustrates the point. It so happens that this patient had been irradiated previously and the effects are well seen with some dead cancer cells.

I find it sometimes very difficult to be certain as to the type of operation that ought to be carried out, and I think it is fair to ask the question "How do we assess operability of a postcricoid neoplasm, and when do we consider the tumour as suitable for the operation of transthyroid pharyngotomy?" We know from the teaching of Trotter and Colledge that this operation is an excellent means of approach to growths involving the epiglottis, the lateral wall of the pharynx, and the aryepiglottic fold, but what about its suitability to lesions situated lower down in the postcricoid space and extending to the upper end of the œsophagus?

When one is faced with this type of growth, the question foremost in one's mind is whether the mass can be removed without sacrificing the larynx. Indirect examination with the laryngeal mirror may show free and mobile vocal cords and normal arytenoids. When this is the case, the tendency is to decide upon a transthyroid approach, particularly when glands in the neck do not appear to be involved. But mobile vocal cords and normal arytenoids are no guarantee that the hypopharynx can successfully be separated from the larynx.

There is nothing more embarrassing than, having started on a transthyroid pharyngotomy, to find when mobilizing the thyroid lobe that the growth has extended insidiously into the posterior edge of the lobe or on to the back of the larynx. The involvement of the gland under the edge of the thyroid isthmus generally means that the larynx is involved as well, and that the hypopharynx cannot safely be separated from the larynx. With this state of affairs, a transthyroid operation has to be converted into a pharyngo-laryngectomy, and this cannot be done unless care has been taken at the very beginning to fashion a skin flap in such a way as to enable one to prepare for the subsequent plastic repair.

The downward extension of the growth cannot always be judged by direct examination. While soft tissue X-ray can prove helpful one cannot be certain of the extent of the growth until it can be palpated by exposure. The size and the type of flap made at the beginning is therefore important.

Colledge made it a rule that neoplasms of the pyriform fossæ and advanced postcricoid growths required a pharyngo-laryngectomy, and it was his custom to fashion a flap for this operation by turning back large skin flaps from the mid-line of the neck, whether a gland dissection was necessary or not. I prefer, however, the large skin flap as suggested by Wookey, with a wide base hinged either on the right or the left side, behind the sternomastoid. There are greater advantages to be had with this exposure as a lateral pharyngotomy can be transformed into a pharyngo-laryngectomy should one find, half-way through the operation, that the larynx cannot be saved.

FIG. 9.

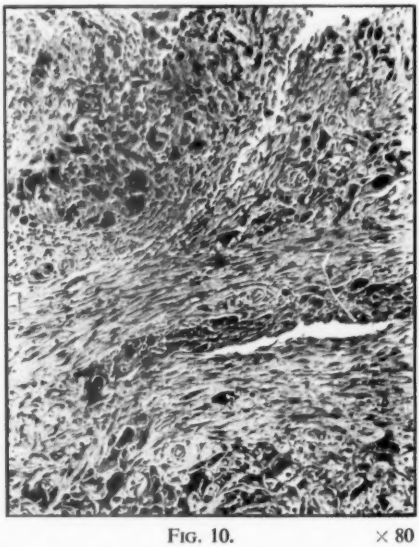

FIG. 10. × 80

Operative results.—I find that in spite of grading, the clinical soft, spreading, ulcerating tumour gives a far higher percentage of recurrences than the hard, infiltrating type, even when both are graded as 1.

The suggestion that it is unwise to advise radical surgery for the more anaplastic Grade 4 is not always true. Fig. 9 shows very superficial ulceration, beginning in one pyriform fossa with œdema of the aryepiglottic folds and extending downwards for nearly two inches. The section of this growth (Fig. 10) shows a carcinoma which here and there has differentiated into obvious squamous cells, but for the most part is anaplastic. Many of the cells are large, and have bizarre nuclei. Others are multinucleated. On cytological structure this tumour might be considered malignant, but in the part sectioned there is only superficial infiltration into the muscle, and this is important.

Showing stoma—Gluck's tube removed

FIG. 11.

The case is that of a woman on whom I operated nearly sixteen years ago, at the age of 59, and she is still alive. She was shown at this Section about two years ago, and there is no doubt that the reason why she has shown no signs of recurrence, in spite of the growth being classified as anaplastic, is the fact that infiltration into the muscle was at a very early stage, or that in this giant-celled type the histological appearance belies its malignancy.

This patient is rather unique inasmuch as she refused to undergo the plastic operation for the closure of the pharyngeal stoma. For sixteen years she has thrived and enjoyed solid food. She has taught herself to care for her Gluck's tube properly, and by this means she has perfect control of her swallowing and secretion of saliva (Fig. 11).

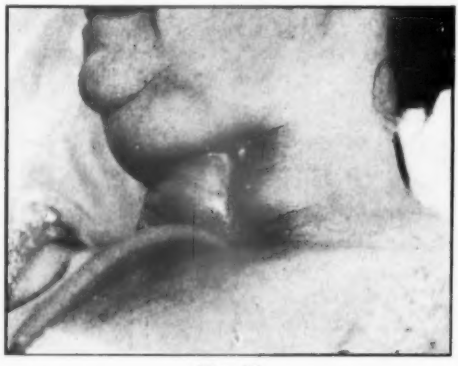

FIG. 12.

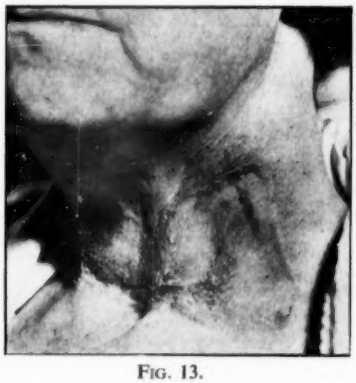

FIG. 13.

Pharyngo-laryngectomy and *transthyroid pharyngotomy*.—One or two points may be mentioned: Firstly, the difficulties encountered in a neck that has recently been irradiated when one has to decide to perform a transthyroid pharyngotomy for a recurrence. The trouble in these cases is confined mostly to the skin reaction (Fig. 12) with its reactionary œdema complicated by the persisting lymphatic stasis. When this occurs it is necessary to wait for months before one proceeds with the plastic operation for closing up the stoma. Even then great attention must be paid to the lower opening, as there is an extreme tendency for this to close up, reducing the lumen to 2 or 3 mm. This can happen although care has been taken at the first operation to cut the œsophagus obliquely. If doubt remains as to the fate of this narrowed lumen it is by far safer to remove the scarred lumen, and skin-graft the raw surface. This can be held in position either with a Souttar's tube or a polythene tube of the same shape and length. Fig. 13 shows the neck of the same patient after the plastic operation has been completed, and the skin lymphatic stasis having been absorbed completely.

Another difficulty encountered during a pharyngo-laryngectomy is the preservation

of the sternomastoid muscle where gland dissection of the neck has had to be carried out. This is particularly so when the large Wookey flap is used.

Fig. 14 is an example of what happens to the skin flap when its blood supply has been interfered with as the result of having to sacrifice too much sternomastoid. The tendency is for the upper attachment to slough off and roll back leaving a large pharyngostome. When this happens co-operation with a plastic surgeon is essential.

Fig. 15 shows the neck closed by means of a large pedicle flap raised from the chest, and in this case I am indebted to Mr. John Grocott for his kind and valuable help.

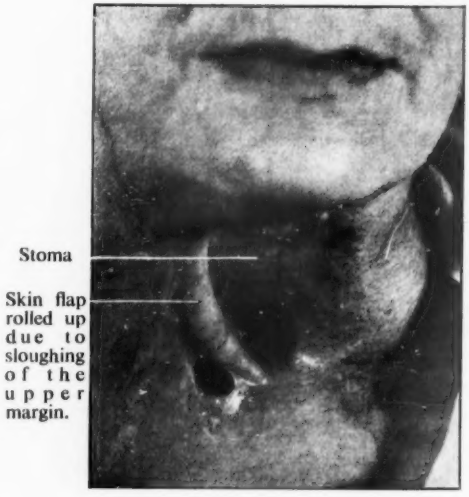

FIG. 14.

FIG. 15.—Pharyngostome closed by pedicle graft from chest wall.

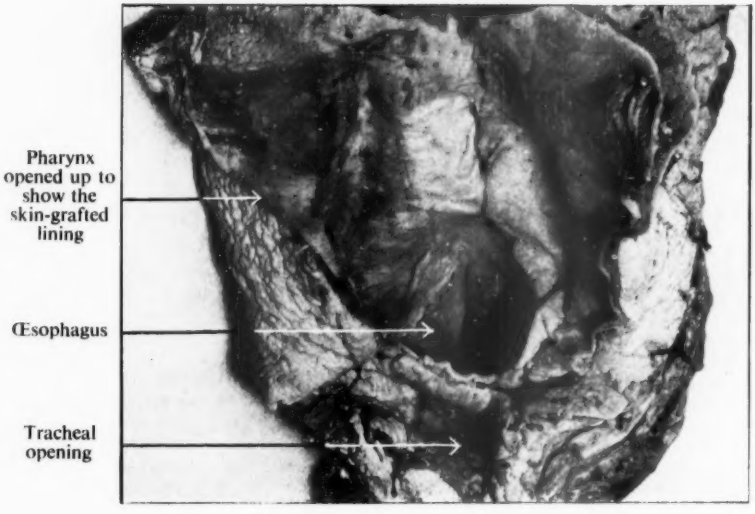

FIG. 16.—Post-mortem specimen. U-shaped flap opened up, showing skin-grafted pharynx and upper œsophagus.

The avoidance of multiple operations.—As Colledge points out in his Lettsomian Lectures it is sometimes necessary to proceed with as many as four stages before a lasting result can be achieved. There is nothing more distressing for the patient after a pharyngo-laryngectomy, than to find herself without a voice, and dribbling saliva through an open pharyngostome. In addition she has to be fed through a tube.

The primary closure of the pharyngostome will minimize this drastic change. This can be done if the original incision is of the "U"-shaped type as used for ordinary laryngectomy. When the lower pharynx and the larynx have been removed a Gluck's tube is inserted into position, and then surrounded by a stent mould. The whole stent now surrounding the Gluck's tube is removed and covered completely by a Thiersch graft removed from the thigh. The stent tube and skin-graft covering are now replaced into position and the "U"-shaped skin flap brought over the whole area and sutured into its original position—the lower end being carefully adjusted to the tracheal stump.

The external pressure.—Particular attention must be paid to the pressure that is applied on the surface of the skin flap and kept constant for at least seven days.

Two other steps are essential to the successful skin-grafting of a new pharynx : A gastrostomy and the provision of nasal suction to withdraw the pharyngeal secretions.

Fig. 16 shows a post-mortem specimen of a pharynx that was successfully grafted.

In conclusion one may emphasize that the only solution to this problem is early diagnosis and the recognition of the precancerous phase. If this, as a clinical entity, is accepted and recognized, one can decide on one of two things:

(1) Repeated œsophagoscopy as a method of routine follow-up when symptoms continue.

(2) When the dysphagia recurs with persisting mucosal changes, the vulnerable hypopharyngeal segment ought to be replaced by skin flap.

This in itself would be a great step to enable one to avoid the mutilating operation of pharyngo-laryngectomy which prevents the return of normal function as compared with a transthyroid pharyngotomy.

Finally the following figures show the low survival rate for extrinsic cancer as compared with intrinsic laryngeal cancer (Table V).

TABLE V

	Pharyngo-laryngectomy No. of cases	Post-op. deaths	Recurrence within 12 months	Recurrence within 5 years	Survived 5 years and more
Extrinsic cancer of the larynx	22	5	8	5	4 =18%
	Lateral pharyngotomy for postcricoid carcinoma and upper end of œsophagus	Post-op. deaths	Recurred within 12 months	Recurred within 5 years	Well after 5 years
	14	4	6	2	2 =14%
Intrinsic cancer of the larynx	Operations: Thyro-fissures, Radium fenestration, Total laryngectomy	46			Well 5 years and more 35 =76%

I would like to express my gratitude to my colleague, Mr. Emlyn Lewis, for his invaluable help and co-operation with the reconstruction and skin grafting of the pharynx following pharyngo-laryngectomy. Also to Professor Jethro Gough and members of his Pathological Department for their help and advice, and to Dr. Lewis Fanning, of the Statistical Department of the Welsh School of Medicine.

V. E. Negus said that it was a matter of great regret that it had not been possible to obtain better results in this disease. One started by seeing Mr. Trotter at work and accepted anything he said as the right teaching; but confidence had been rather shaken as time went on. Mr. Negus would like to repeat what Mr. Owen had quoted him as saying in 1931 about the precancerous condition; he had not the slightest doubt about the relationship and Mr. Owen had confirmed this opinion in his Address. In 1938 he (Mr. Negus) was in the United States and in a discussion there on what was called the Plummer-Vinson syndrome, some surprise was expressed at the idea that this might be a precancerous condition. He did not feel that anyone could possibly be in any doubt; one saw cases too frequently.

The term "postcricoid" was misleading; most of the growths started at the mouth of the œsophagus on the upper surface of the cricopharyngeal fold, in the region affected by chronic inflammation. This was the lowest part of the pharynx and he would suggest that the proper term was "chronic hypopharyngitis". The condition commenced on the fold away from the larynx, on the posterior wall.

If treatment were carried out and failed to arrest the disease by dilatation or other means, and if it was thought that ulceration was going on, possibly with a little irregularity of the epithelium which, although not proved to be carcinomatous, seemed to have a probability of becoming malignant, the right thing to do appeared to be to remove that segment of the lower pharynx and upper œsophagus. It would be easy to separate the œsophagus from the back of the trachea and larynx with little chance of recurrence. The malignant changes would be on the posterior wall and reconstruction would give the patient the ability to swallow well, making the operation justifiable.

If malignant disease were established, one could see if there were any extension into the larynx or trachea by direct examination; if there were any infiltration it would be futile to leave the larynx in position. He had tried various conservative operations and had been very disappointed with results. It was a small matter whether one used the single large flap of Trotter or two shorter flaps. The latter appeared to be more reasonable and one was thus able to reconstruct the pharynx and œsophagus and restore swallowing. His experience had been that many, indeed the great majority, of these cases recurred. It was not possible to tell beforehand which case would and which would not recur.

There was a second possibility; if the top of the œsophagus and the lower end of the pharynx were removed, and reconstruction was carried out, the larynx was left lying against the raw front of the vertebral column. A case was referred to him recently where this had happened. The patient could not swallow because the skin tube was not complete; it was possible to complete it, but when the patient made an attempt to swallow everything he drank ran straight into the larynx. All his saliva overflowed throughout the day and night and the man was in a most miserable state. There was also double recurrent paralysis; he could not close the larynx and he could not pull it up against the base of the tongue because it was fixed. His distress was so great that the speaker removed the larynx and found in its lymphatic vessels some carcinomatous cells. It would have been better if the larynx had been removed earlier. He had seen the same condition occur in a woman who had had a very small growth irradiated. The growth was limited to one small patch on the posterior wall, but removed within a year. At operation it was possible to remove the segment and restore continuity by turning in two skin flaps. She had a left recurrent nerve paralysis because the skin flap lay over it, and the right recurrent nerve later became paralysed. She was in the same miserable state as the other patient; later she died from recurrences.

After these and other unfortunate experiences he felt that the limited operation was not justifiable. He did not believe that irradiation would cure these patients and there were therefore two alternatives: one, to do nothing, and the other to remove the lower part of the pharynx, the larynx and the top of the œsophagus. Pharyngo-laryngectomy could allow a patient to live happily; they could even learn œsophageal speech or have an artificial larynx, and he believed that it was the right operation in this dire disease.

The next point was with regard to restoring continuity. One had tried the ordinary procedure of turning in flaps, but this was tedious and was sometimes followed by stricture. Mr. Charles Rob and Mr. Bateman at St. Thomas's Hospital had tried a means of primary repair, at first using tantalum gauze and in later cases a plastic tube; discussing the problem with Professor Kilner, it was agreed that it was illogical to do any repair work without skin graft. About a week previously Mr. Negus operated on a patient who had a growth at the cricopharyngeal fold; it was extensive and therefore the larynx, part of the pharynx and the top of the œsophagus were removed, together with three rings of the trachea. The trachea was fixed to the skin and the top of the œsophagus was attached by some stitches to the prevertebral fascia. A plastic tube was inserted, reaching from the pharynx to the œsophagus with a skin graft around it; the skin flaps were closed over it. Irregular flaps were made, on the advice of Sir Archibald McIndoe, so that the line of incision did not coincide with the line of the skin graft. If one could carry out primary repair with safety, even if slight alteration were required later to assist healing, it would be of very great benefit both to surgeon and patient.

One other point was that he had been advised by McIndoe that it was best to leave the tube, covered with a skin graft, in position for six months. The patient could swallow through the tube, which was anchored with a piece of stainless steel wire.

In Mr. Negus' opinion the present position was that for carcinoma of the hypopharynx the proper procedure was pharyngo-laryngectomy with primary repair.

J. F. Simpson also thanked the President for his most interesting and excellent presentation of his subject matter. He had covered so much ground that his audience could only hope to speak on one or two points. He noticed that the President drew a distinction between the various forms of the growth, the hard infiltrating type and the softer fungating type. The speaker had recently had the misfortune to operate on a case of the latter type of growth which appeared very small when he looked at it through the pharyngoscope but when he removed the pharynx much of this was studded with pin-point deposits of growth so that the mucous membrane had a mammillated appearance. He thought this type in which there was quite a small primary ulceration and at a considerable distance multiple small deposits giving a mammillated appearance to the mucous membrane constituted a distinct clinical type. He took it he had wasted his time by operating on that throat.

Mr. Negus had clarified the question of whether to remove the larynx or not and his views fell into line with Mr. Lionel Colledge's teaching. There could be no doubt that if the growth had become attached to the back of the larynx the correct procedure was to remove the larynx and pharynx and not to risk leaving a small piece of neoplasm on the larynx.

The pictures shown at the meeting indicated that the removal of a larynx to-day was not nowadays such a gross disability. He noticed that Mr. Negus spoke of the "œsophageal" voice, he believed the speech therapists were now cultivating a "pharyngeal" form of voice.

Professor F. C. Ormerod congratulated the President on his very remarkable results. He, like others, had struggled with these extensive removals of the larynx and pharynx, which were tedious, required a number of operations and much care over long periods and the results were not always satisfactory. There was a tendency to recurrence on the mucous membrane side of the junction with the skin flaps, either above or below, and he felt that this was due to a submucous extension of the growth far beyond its visible or palpable limits.

He felt that there were still hopes that radiation would cure these growths. He had worked for more than twenty years with radium bombs, from 1 gramme up to 5 grammes and the results had been very poor. Now that 10-gramme units were available, more successful results were being achieved. In January 1948 two old ladies, over 70 years of age, were treated with the 10-gramme bomb, one for a postcricoid and one for pyriform fossa growth. Both were perfectly well to-day and swallowing normally. It was anticipated that similar results might be achieved with the new very high voltage X-ray apparatus.

R. R. Simpson supported Professor Ormerod in his plea that irradiation should not be altogether discarded. He was reminded of the earliest hypopharyngeal carcinoma on which Mr. Colledge operated. It was a growth about the size of one's little finger-nail. He had advised irradiation but he gave the patient the alternative of seeing Mr. Colledge who advised resection. It was carried out in Mr. Colledge's masterly fashion but the skin flap sloughed and the patient was sent back to the speaker until such time as repair could be made. Within two months the patient suddenly had a hæmoptysis and when his chest was X-rayed it was found that he had extensive secondaries all over the lungs.

On the other point of the incidence of hypopharyngeal carcinoma with anæmia and dysphagia, it had interested him very much for years. It was rather remarkable that there was such a wide variation in the published incidence. For instance, the President's figures at Cardiff were at

variance with Flett's of Derby, and both these sets of figures were in variance with the figures which he got in the East Yorkshire–Hull area which again were entirely at variance with Vinson's figures in America. Vinson wrote him at the end of 1939 to say that he never saw carcinoma and they still regarded the condition as hysterical manifestation although they did agree that mucosal change occurred which they thought was due to defective keratinization and probable riboflavin deficiency. In the European figures there was a wide divergence. The Swedish figures showed a much higher incidence than was seen in this country, the figures for the different countries gradually decreased until in the Mediterranean area they appeared not to see carcinoma. In the East one saw anæmia with dysphagia but he did not see any cases with carcinoma. Was this a geographical variation in one type of disease? It did occur in other diseases; were they dealing with some geographical variation of the precancerous phase?

H. V. Forster said he would join other members in their appreciation of the Presidential Address, and not having done any major operations to relieve this dismal affliction of the female hypopharynx he would praise the diligence and courage of those who had performed them.

He had not found in his experience that the syndrome of dysphagia with anæmia had been a regular precursor of postcricoid cancer, and from his reading imagined this was the opinion of some other observers.

He had seen for the first time in 1935 at the Finsen Institute in Copenhagen soft tissue radiographs demonstrating amelioration in this disease where improvements in insulation of the apparatus had made possible the use of higher voltages.

He would express the hope that having reflected the skin of the neck, and perhaps separated deeper tissues, short period massive doses of X-rays may be applicable to cancer of the hypopharynx.

The President, in reply, expressed appreciation for the kind things that had been said by Mr. Negus and others. He was grateful for the contributions made during the discussion. In his view the most important fact brought out was the agreement regarding the necessity of recognizing the precancerous phase in cases of chronic hypopharyngitis, with or without anæmia.

The replacing of the vulnerable segment with skin flap, during that phase, was not a difficult procedure, but one had to be very certain of the presence of this early phase before advising operative interference.

Mr. Negus's point regarding bilateral recurrent laryngeal nerve involvement was not a usual picture, but where it did occur it was, as a rule, caused by a recurrence of the growth. It need not take place as part of the operative technique, and the possibility should not act as a deterrent in dealing with cases of chronic hypopharyngitis. He was glad to hear that primary repair following pharyngo-laryngectomy was recognized as the reasonable thing to carry out.

Mr. J. F. Simpson's remark regarding his own case emphasized the importance of recognizing the mode of downward extension that is liable to take place. This sometimes could be palpated during operation, before the pharynx was opened. If in doubt as to whether one could get below the growth, then the case was best left alone and ought to be referred for deep therapy treatment.

Section of Dermatology

President—W. N. GOLDSMITH, M.D., F.R.C.P.

[*November* 17, 1949]

Chronic Papular Dystrophic Dermatosis with Nail Changes. ? Lichen Planus.—L. FORMAN, M.D., and H. HABER, M.D.

Mrs. A. B., aged 53.

First seen October 1946 with a twenty years' history. On both legs from the knees to the ankles there were many closely set dull red papules, some flat, others domed. The papules were discrete or confluent to form a line or a mesh; over the right ankle they formed a continuous plaque covered by a crust and superficially ulcerated. A few papules were found on the nape of the neck. There was some irritation.

All the toe-nails were thickened and brown, and two finger-nails were discoloured, opaque and thick, and pinched up from the nail bed. No fungus was found in the nails.

The legs have been protected by Unna's paste and after six months the condition showed regression, with atrophy. Many of the papules developed milium bodies as they faded; others showed subepidermal blisters. Small areas of atrophy corresponded with the individual papules which had involuted and recalled the atrophy of lichen planus or lichen sclerosis.

To-day, papules are seen over the left knee, and right shin and ankle, with atrophy of the skin.

The clinical diagnosis suggested that from time to time there has been lichen planus, prurigo nodularis and lichen amyloidosus. No amyloid was to be seen in the sections.

Dr. Haber presented slides to illustrate the peculiar histologic features. Several biopsies had been performed in the last three years. All showed different features.

First section: Atrophic epidermis, flattening of the epidermo-dermal junction, sclerotic papillary body with gaping blood vessels and lymphocytic infiltrations; the rest of the cutis apparently normal. Immediately under the epidermis was a typical milium the origin of which could not be traced.

Second section: Similar epidermo-dermal changes, but in addition there was a clear separation of the epidermis from the papillary body.

Third section: A fully developed subepidermal bulla has formed. The roof was provided by an atrophic epidermis, the base by a sclerotic papillary body. The bulla was clearly secondary to the atrophic changes. In addition there were several rete pegs left within the papillary body, as they were torn away by the separating bulla, a process similar to that seen in epidermolysis bullosa hereditaria. These remnants of rete pegs were the origin of milia, which were a conspicuous feature in the case.

Dr. Haber concluded that there was definite histological evidence of lichen planus atrophicus with superimposed bullous formations terminating in papules containing milia. The condition is chronic and has to be distinguished from lichen planus pemphigoides, which is an acute eruption.

Ulcers of Foot with Congenital Arteriovenous Communication of the Right Lower Limb.—L. FORMAN, M.D., and H. E. HOLLING, M.D.

J. C., female, aged 21.

At the age of 4 years a hot swelling was noticed on the dorsum of the right foot. An orthopædic surgeon stated at that time that there was no bony abnormality and encased her leg up to her knee in plaster, which the patient wore for some months. Within a year the swelling had disappeared, but ever since that time the foot has been noticed to be hot and to sweat more than the other foot. The patient suffers from chilblains in the winter on her left foot but not on the affected limb. For the same length of time the skin on the dorsum of the right foot has been pigmented brown. Although she wears the same size shoes, the patient has noticed that the dorsum of the right foot projects above her shoe more than the left one.

Fourteen months ago a scab appeared on the dorsum of the right foot and when the patient removed this a shallow ulcer was left which refused to heal. Two months later a second ulcer appeared and later a third ulcer at the base of the second toe and a fourth ulcer on the dorsum of the second toe. Various local treatments were tried without effect and local penicillin was followed by generalized urticaria.

In March 1949 she was admitted to hospital and all the ulcers healed with saline dressings. Soon after discharge two of the ulcers broke down again.

FIG. 1.

In September 1949 she was admitted to Guy's Hospital. On examination there was an area of bluish-brown discoloration and thickening of the skin on the dorsum of the right foot with an ulcer in the centre of the area and a second ulcer on the second right toe (Fig. 1). The ulcer was approximately 1½ in. long and ½ in. wide, with its greatest length in the long axis of the limb. The edges were thickened and a pyogenic membrane covered the floor of the ulcer. So bizarre was the appearance that at first the diagnosis of dermatitis artefacta was entertained. However, there was a marked difference in the temperature of the two feet. The right tibia was 1 in. longer than the left. The dorsalis pedis and anterior tibial arteries on the affected side were enlarged and the veins were slightly more prominent. On the sole of the foot there were two areas about the size of a penny, one under the metatarsal heads and one on the heel, markedly hotter than the rest of the foot and showing capillary pulsation on pressure. The blood pressure in the two lower limbs was the same—160/90. Apart from generalized dermographia, there were no other abnormalities.

Investigations.—Hb 76%; R.B.C. 3,800,000; W.B.C. 8,300—normal differential. Wassermann reaction and Kahn negative. Culture from ulcer—coliforms only. X-rays confirmed increase in length of tibia but showed no definite change in the size of the bones of the feet. There was no bony abnormality. Infra-red photographs showed slight increase in the veins of the right leg.

Dr. H. E. Holling: The important points in the diagnosis of this case of arteriovenous fistula were (*a*) the condition had been present since birth, or shortly after birth; (*b*) the ulcerated foot was warmer than the normal foot; (*c*) the right tibia was longer than the left; and (*d*) the veins of the right calf were dilated (though not varicose).

The right foot was found to be 5° C. warmer than the left, and the skin of the dorsum, ball and outer half of the heel of the right foot was 3° C. hotter than the skin around. (Right foot 31 to 34° C., left foot 26° C., room temperature 24° C.) This finding indicated that the blood flow to these areas was greatly increased. On the outer side of the right heel large skin capillary vessels could be seen with the naked eye. The blood flow to the right foot was measured by means of a plethysmograph and found to be 180 ml./minute whereas that to the left foot was only 10 ml./minute. Arterial blood (95% saturated with oxygen) was obtained from the dilated vein at the internal malleolus.

In my experience this case is unusual in not having varicose veins. The usual picture is of a patient of 20 to 30 years of age with varicose veins and malleolar ulcers. The diagnosis is sometimes made during injection for the varicose veins when it is found that blood withdrawn from the veins is of bright arterial colour.

In order to show the extent of the lesions it will be necessary to do an arteriogram in this case. Surgical removal of the fistulæ is likely to be difficult because the angiomatous tissue appears to be embedded in the deep tissues of the foot. If the ulceration becomes intractable we shall have to consider amputation, either of the foot or from below the knee.

It is strange that skin ulceration should be associated with apparently increased skin blood flow. I believe, however, that the actual skin blood flow is diminished because blood is being diverted through the fistula instead of passing through the overlying skin. The increased skin temperature, which usually denotes an increased skin blood flow, is the result of the increased blood flow in the fistulæ underlying the skin. We cannot put this supposition to the test because we have no direct way of measuring skin blood flow. In a comparable case of pulmonary arteriovenous fistulæ, however, the blood flow through both fistula and normal lung tissue could be measured. When this was done it was found that a large blood

flow through the fistula is associated with a diminished blood flow through the normal lung tissue.

Dr. R. E. Bowers: There is a fairly loud blowing murmur beneath the metatarsal arch at the site of the area of discoloured skin. I could hear no murmur over the heel but possibly one would be able to do so in a quieter room. The murmur might be of value in localizing the arteriovenous communication.

Purpura Annularis Telangiectodes (Arciform Type—Touraine).—BRIAN RUSSELL, M.D., and R. N. R. GRANT, M.B.

Miss S. L., aged 18.

History.—In December 1948 she noticed a non-itching discoloured patch on the inner side of the right thigh which gradually enlarged. She was first seen in June 1949 and the accompanying photographs show the progress of the lesion during the following four months. The lesion was flat and roughly annular, about 4 in. in diameter, the centre pigmented but not atrophic, the edge consisting of purpuric and telangiectatic elements (Fig. 1). The lesion gradually spread peripherally and cleared centrally, the edge breaking up into segments and almost disappearing after about eleven months (Fig. 2).

FIG. 1.—Condition on 21.6.49.

FIG. 2.—Condition on 4.10.49. (Biopsy scar at top on right.)

She now presents four more recent lesions on the thighs in discoid and annular form.

General health is good. She takes no drugs. The teeth are sound and the throat normal. The urine is normal. Wassermann and Kahn reactions are negative.

Histology.—The vessels of the superficial corium show capillary dilatation and some surrounding infiltration, mainly of round cells, with some polymorphonuclear cells. There is slight extravasation of red cells which show a little scatter. Hæmosiderin is not seen and the only pigment noted is the melanin in the basal layers of the skin and the melanophores, and this is not grossly increased.

Comment.—Touraine, in reviewing the capillary ectasias (*La Presse Médicale*, 1949, **65**, 934) points out the differences between this condition, of which he has seen 5 cases and collected others from the literature, and the Purpura Annularis Telangiectodes of Majocchi, in which the lesions are smaller, more numerous and leave hæmosiderin pigmentation and some atrophy. It occurs more often in the female than in the male in the proportion three to one, whereas Majocchi's disease is equally distributed between the sexes. In both diseases the majority of cases occur in young adults (under 40) but Majocchi's disease shows a higher incidence in the older age-groups. Touraine's illustrations correspond closely to the photographs shown of this case and to the present lesions, leaving little doubt that this patient is suffering from the condition which he calls Purpura Telangiectasique Arciforme.

Sarcoidosis following Injury.—R. D. SWEET, M.R.C.P.

A man, aged 32, was blown up by a mine in April 1945. The mine was of the wooden box type, filled with gun cotton, and buried in a field in loose soil. His left foot was blown off and he was heavily peppered with small particles mostly on the hands, face, chest and legs, and also in both eyes.

Foreign bodies were removed from both eyes and the sight was restored to Right 6/6, Left 6/5. There were many dark marks on the hands, especially the left, and also on his chest and both thighs, and over the whole of the face. These, however, caused no inconvenience and no swellings. He remained fit until January 1949, when, almost four years after the injuries, he noticed blurring of vision in the left eye and at about the same time a swelling by his left elbow. Soon afterwards many firm painless swellings appeared on the left hand, the face, legs, right hand and on both forearms. These increased in size until April 1949 when they became stationary. Vision in the left eye became progressively worse and he could see a white patch over the iris which continued to increase in size until by July the eye was quite blind.

Past history.—Nothing of note. No suggestion of tuberculosis at any time.

Present state.—Opacity in anterior chamber of left eye, apparently arising from the iris. Numerous small nodules scattered over face and eyelids, some obviously in relation to imbedded dark-coloured foreign bodies. *Left hand*: Diffuse firm, non-tender swellings along dorsa of fingers and on dorsum of hand. Many dark foreign bodies. *Forearms, right hand, both legs*: Widely scattered small flesh-coloured nodules. Enlarged rubbery glands in axillæ and sides of neck and epitrochlear regions. Liver and spleen not palpable. No other abnormal physical signs.

Investigations.—Mantoux positive 1/10,000. X-ray chest: Possibly some hilar gland enlargement. X-ray hands: Middle phalanx left fourth digit shows a localized area of translucency in the mid-shaft. E.S.R. 5 mm. in one hour.

Histology (Dr. I. W. Whimster).—(1) *Skin*: The dermis contains many discrete and confluent foci of tuberculoid granulation tissue in which are several areas of necrosis, many appearing to have arisen in the connective tissue between tubercles rather than inside them.

Scattered throughout the lesion, and to a lesser extent the adjacent skin, there are many variably sized polyhedral, doubly refractile, crystalline particles, a few of which are within giant cells. No acid-fast bacilli could be demonstrated in the five sections examined for them.

(2) *Lymphatic gland*: Most of the gland tissue is replaced by confluent and discrete foci of histiocytes with giant cells, lymphocytes and eosinophils. There are no areas of necrosis nor any doubly refractile particles in the sections examined.

Treatment.—He has been treated with calciferol, 1,200,000 units a week and streptomycin 1 gramme daily, and the lesion in the left eye has decreased in size, as have the scattered lesions on the face. His hands and the enlarged glands remain unchanged.

Comment.—The biopsy section of the skin shows doubly refractile particles in close association with giant cells. Yet, both clinically and histologically, the picture is like sarcoid or tuberculosis, especially the former in that there is no fibrous reaction. The section of the lymph gland is typical of sarcoidosis, and here there are no doubly refractile particles.

When silicates are introduced into the body, be it into the lungs, or within the peritoneum as talc on the surgeon's gloves, the reaction produced is intense fibrosis. If the regional glands become involved they become fibrotic and doubly refractile bodies are seen within them. The gland in my case shows no fibrosis.

Furthermore, this fibrotic reaction is more or less immediate. Walker (1948) and Mackey and Gibson (1948) report cases of intraperitoneal "siliceous granuloma", probably due to talc, occurring seven weeks and only thirteen days after operation.

Yet surely, except in the lungs, only certain people react to silicates. Innumerable abdomens have been contaminated with talc and many skins have been impregnated with debris and soil by explosions without developing sarcoid-like granulomata. Is it certain that in the peritoneum infection did not cause adhesions and that talc lying around was not phagocytosed by cells mobilized for another purpose?

Again, how can we explain the immediate fibrous peritoneal response and the long-delayed tuberculoid skin response, so well shown in my case where almost four years with perfect sight went by, before a tumour developed in his uveal tract?

There is a curious association between tuberculosis and trauma. Tuberculosis colliquativa not uncommonly occurs at the site of some previous minor injury and trauma sometimes seems to determine the site of tuberculous infections of bone, in patients apparently free from active tuberculosis. Tuberculosis usually complicates silicosis of the lungs and Fletcher (1948) suggested that progressive massive fibrosis only occurs because of the superadded tuberculous infection.

If it is agreed that sarcoidosis is a manifestation of tuberculosis, it does seem possible to regard this case of mine and others similar to it that we have seen at this Section recently in this way:—

Trauma has occurred and foreign bodies are present. Tuberculous infection has occurred in the past. The patient's resistance and reactivity fluctuate and at some stage he reaches a state when the presence of the foreign body tips the scales against him locally and a tuberculoid focus results.

Perhaps it is only at this stage that the giant cell ingests the doubly refractile particle! The important thing is that the patient's response is a pathological and not a normal one to the presence of foreign bodies.

Tuberculous or Silicotic Granulomata.—G. C. WELLS, M.B., and W. N. GOLDSMITH, M.D.

Mrs. A. D., aged 32.

History.—Six months ago lumps appeared in scars that had been present for many years.

In 1937 she had a cycle accident on a gravel road causing multiple lacerations which healed with scarring.

In 1939 a tuberculous gland of the left side of the neck broke down (tubercle bacilli were recovered from the pus). After surgical drainage the wound healed soundly.

Her general health has been good.

On examination (July 1949).—On the left side of the face, left shoulder and right elbow there were raised nodular lesions extending out from the edges of old scars, the nodules having the "apple jelly" colour characteristic of lupus vulgaris. On the back of the right hand and wrist were several raised, rather more lichenoid granulomata, again in the substance of old scars. Lesions were noted only in the scars from the old cycle accident, not in other scars nor in unscarred areas (Fig. 1). There was discrete, rubbery enlargement of the right epitrochlear gland.

FIG. 1.—Lesions of lupus vulgaris in old scars.

Investigations.—Radiograph of the chest in July 1949 showed marked enlargement of the hilar glands and a paratracheal gland. Mantoux reaction was positive (1 : 1,000). Biopsies were made from three of the skin lesions and the right epitrochlear gland was removed.

Histology.—In the skin sections there are foci of tuberculous granulation tissue at various levels in the dermis. There is rather more central necrosis than is commonly seen in lupus vulgaris. In one section there are some minute doubly refractile particles in and among

the histiocytes but silica is not convincingly demonstrated. The lymph gland on the other hand shows replacement of its normal structures by numerous neatly arranged islands of epithelioid cells exactly in the manner of sarcoid.

Fresh material was taken from one skin biopsy and from the lymph gland, and with this Dr. Wetherley-Mein inoculated culture media and animals. No growth of tubercle bacilli was, however, demonstrable.

Progress.—While under observation in July and August 1949, the patient developed erythema nodosum of the legs, which subsided in six weeks.

In October 1949 radiograph of the chest showed the hilar glands to be no longer enlarged.

While in hospital recently there has been no fever or cough, blood findings have been normal and general health has been satisfactory.

Calciferol therapy was started in October and there has been a striking response. After just over 5,000,000 units of vitamin D, the lesions have flattened out and there is hardly any trace of granuloma.

Comment.—Of particular interest in this case is the recent appearance of multiple lupus vulgaris lesions in scars that had been present for twelve years, only those scars which resulted from the road accident being affected. A scar on one finger following an accident with a printing machine when she was 16 years old shows tattooing from inclusion of black ink, but no lupus. Neither has lupus appeared in the surgical scar on the neck.

It seems likely that there has been a recent dissemination of tubercle bacilli by the blood stream in a subject whose resistance is good; and a proliferative reaction has only taken place at favourable sites in the skin, namely those scars that probably contain some silica inclusions. Kettle (1932, *J. Path. Bact.*, **35**, 395) demonstrated that in mice the tissue reaction to silica suspensions injected subcutaneously was distinct from the reactions provoked by "inert" dusts, and that the silica reaction favoured the accumulation or multiplication of tubercle bacilli, after living bacilli had been injected into the circulation.

In this case a changing reaction to tuberculosis is suggested by the transient hilar gland enlargement and erythema nodosum. The sarcoid reaction in the lymph gland close to the lupus reaction in the skin is also of interest.

Dr. Sommerville: In Dr. Sweet's case there is no doubt about the crystalline material in the section and I thought there was some evidence, no matter how slight, of some highly refractile material in the other section. Admittedly in tuberculoma silicoticum there should be a sarcoidosis reaction and we think it might be related to tuberculosis. The reaction of Kveim can be produced by several types of materials injected and yet give a specific tissue response. I do think that this type of lesion, which is of the lupoid form rather than the sarcoid type, is a specific tissue response occurring in a peculiar subject probably of the tuberculous type.

Hidradenitis Suppurativa (Apocrine Acne).—W. N. GOLDSMITH, M.D.

W. H., man, aged 28, admitted to the Hospital for Tropical Diseases on 1.11.49, under Professor Hamilton Fairley.

History.—He was born in England, went to India at the age of 3, and remained there until August 1948, when he returned to England. While abroad he had severe *enteric fever* in 1935 and *pneumonia* in 1937.

In 1936 a *perineal abscess* formed, which ruptured spontaneously and healed, and one month later a similar abscess formed on the right side of the scrotum. Treatment in hospital in India was not effective, and lesions continued to recur. Later they spread on to the inside of the thighs, and in 1942 on to the buttocks, and in 1945 into the axillæ.

The general evolution is for a lesion to form pus, drain spontaneously, and, instead of completely healing, to track under the skin and break out at a distance as a similar lesion.

The condition has extended without the patient's seeking any medical advice. But since the beginning of this year, he has been treated at Kingston and Farnham Hospitals with sulphonamides, penicillin, zinc peroxide, and calciferol. The tentative diagnosis was acne conglobata.

Present State.

General condition.—He feels well; no constitutional disturbance, except when sepsis becomes excessive and he gets some fever. Walking is somewhat impeded. Weight: 12 st. 7 lb.; lost 11 lb. since last May. Appetite good.

Physical examination.—Carious teeth; some enlargement of axillary and inguinal glands; no enlargement of liver or spleen; no albuminuria, or other signs of amyloid degeneration.

Skin—Right axilla: Healed lesions with some scarring, contraction, and comedo formation. Left axilla: Similar, but some of the lesions are active.

Buttocks, perineum, and inner, upper aspect of thighs: Large areas of indurated, scarred, bluish skin. The area is riddled with sinuses discharging green, creamy pus, and pressure on any one part causes pus to ooze at a distance.

Investigations.—Blood-count: R.B.C. 3·89 millions; Hb 80%; C.I. 1·03; W.B.C. 12,200 (P. 67, L. 25, M. 4, E. 4%).

Fæces: Semi-formed, normal colour. No pathogenic ova or protozoa, and no cellular exudate.

Urine: No sugar or albumin. Deposit normal.

W.R. negative.

Pus: Mixed bacterial flora of Gram-positive and Gram-negative cocci and bacilli. No mycelium found. No acid-fast organisms. Culture: Sparse growth of *C. xerosis*.

Mycological investigation.—No fungus seen in smear or grown after ten days' incubation.

Since admission, purulent discharge has increased in association with fever, rising nightly to 99·6°–100·4° F. Treatment resumed with penicillin and sulphonamide, with much improvement.

Points in favour of the diagnosis are the distribution, chronicity, and perhaps the co-existence of acne over the scapular region.

Special points of interest are the very slight constitutional disturbance and painlessness.

Hidradenitis suppurativa is similar to other acnes in that it is a suppurative condition of the hair follicles, very chronic, producing in some cases a lot of pus but with remarkably little local or constitutional disturbance. It is the distribution and the histological appearances that make us associate it with the apocrine glands and distinguish it from acne vulgaris and acne conglobata. The bacteriology appears to be as negative in this as in the other two kinds of acne.

With regard to endocrinology we feel fairly convinced that the endocrines play a considerable role in acne vulgaris; in acne conglobata it is not quite so clear, but it mainly affects adult men. Finally, in this apocrine acne there does not seem to be any endocrine upset and the sex incidence is about equal.

Mr. Naunton Morgan has suggested that the best plan will be to lay open the sinuses, region by region, and allow them to heal up from the bottom.

I have never seen such an extensive case. When the condition is limited to the axillæ we usually treat it with X-rays; I do not think this man has ever had X-rays. Should we resort to surgery alone, X-rays alone, or a combination of the two?

Dr. H. J. Wallace: In a similar patient at St. Thomas's Hospital, resolution was secured only by having all the sinuses laid open, the whole treatment lasting for about a year. One axilla was similarly treated without any benefit, but the inflammation in both axillæ appeared to respond to short-wave diathermy and antiseptic compresses.

Wing-Commander H. E. Bellringer: I saw a similar case aged about 45 who had had the condition since he was 20.

He had been bed-bound for the last ten years and had been treated about twelve years earlier by having the sinuses in the axillæ laid open. When I saw him they were completely healed, there was a mass of scars but no suppuration or sinus. There were tremendous tunnellings on the buttocks, groins and running through the perineum, the whole area looked like a rabbit warren.

On Dr. Barber's suggestion I put him on to pregnanediol and he seemed to improve gradually. We decided to lay open as many sinuses as possible and the man made a slow but uneventful recovery.

I saw him recently, some eleven months after the operation; he is now ambulant although he is not yet ready for work. There is no suppuration or local discomfort. The œstrogen therapy was stopped about three months ago, he never suffered any secondary effects from that or any toxic symptoms. I cannot say what part it played in his cure, probably very little because there was radical cure in the axillæ.

Dr. D. S. Wilkinson: I was looking after this patient some months ago. Every known antibiotic and antiseptic was tried and the result was the same as we have just heard described. There was slow improvement, then a relapse or a gradual slipping back. He has had œstrogen therapy for a period without any effect, and it does seem that surgery is the only thing which can help him.

Dr. G. B. Dowling: One surgical procedure has not been mentioned so far, namely, excision and skin grafting. An intractable hidradenitis of the left axilla in a young woman who was under my observation a few years ago was so treated with excellent result. The other axilla which was mildly affected cleared up spontaneously shortly after the operation.

Dr. Hugh Gordon: I think that a combination of surgery and X-rays should be tried in this case. The preliminary surgical measures would consist of a thorough "saucerization" of all the lesions, thoroughly exposing all the tracks, followed by applications of pure carbolic acid. The optimum dosage of X-ray is a very difficult one to decide. My own inclination would be a comparatively high dose for a fairly short time; for instance 250 r every five days for a total of four doses. Possibly the whole area need not be irradiated, but the dose limited to the worst areas of granulation.

Dr. L. Forman: I showed a case at the Section with the diagnosis of acne conglobata at the meetings of March and December 1947. He showed similar, but much more extensive involvement of axillæ, peri-anal skin and buttocks, with ramifying abscesses healing with epithelial bridges.

He had received X-ray therapy and was operated on on two occasions but relapsed and remained in hospital for long periods. Besides the offensive smell he developed a severe anæmia and loss of weight and it was feared that he would develop amyloid disease.

An implant of 300 mg. of stilbœstrol led to definite improvement.

Dr. Dowling: The case about which Dr. Forman has spoken ultimately came under my care having relapsed completely. The very severe acne however has again been brought under control by stilbœstrol 5 mg. daily.

The President: There is a close relationship between this apocrine acne, acne vulgaris and acne conglobata, but they are not identical. This man has mild acne vulgaris over the scapular region.

Dr. Dowling: Is there not a series of cases comprising acne conglobata, hidradenitis axillaris of the type now under discussion, severe cystic acne of the face and neck, and perifolliculitis abscedens et suffodiens capitis having in common the tendency to develop abscesses, sinuses, tunnels, scars, &c., and perhaps linked by some common ætiological factor?

? Parapsoriasis.—CLARA M. WARREN, M.R.C.S., L.R.C.P.

Jill D., aged 16.

The mother first noticed pink patches on the trunk when the girl was 7. They were more pronounced in the winter months, and did not improve after tonsillectomy.

When I first saw her at the age of 10 years 6 months (in 1945) there were brownish papules scattered over the abdomen, back and chest. These did not fade completely on pressure and appeared to be a form of pigmented urticaria. Dermographism could be elicited. Her general health and development were normal. Some improvement occurred after general ultraviolet-light therapy.

I did not see her again for three years (1948). She then showed thickened erythematous areas over the trunk, with smaller discrete patches resembling pityriasis rosea. The plaques showed some brownish staining but there were no isolated pigmented urticaria papules. There was some evidence of ulceration with scab formation, but no pruritus.

A year later, at 16, there are extensive areas of telangiectasis and brownish pigmentation, affecting abdomen, chest and back, and extending symmetrically down on to the thighs. Papular urticaria has been present on the thighs and legs. The dryness of the skin has developed within the last few weeks. Monthly periods have been present for six months. Section of a recent lesion does not show mast cells.

Dr. Warren: I did consider the diagnosis of parapsoriasis and, following Dr. Barber's suggestion that cases responded to calciferol, I tried it for four or five months and it has had no effect on the lesions. I think many members thought of the suggestion of parapsoriasis and also of some abnormal form of reticulosis, or some other blood disorder, but nobody was very definite.

The President: It was parapsoriasis which first suggested itself to me. Some of the lesions did seem infiltrated.

POSTSCRIPT.—March 1950. Blood count shows no abnormality—C. M. W.

Keloid Associated with Acne in a Young Girl.—D. L. REES, M.B., for H. J. WALLACE, M.R.C.P.

Miss P. R., aged 27.

In November 1945 she was treated for a moderately severe cystic acne involving the face, chest and shoulders, first with routine local therapy and later with superficial X-rays (5 doses 100 r).

At that time small, firm lesions were scattered over the shoulders and chest which were thought to be inspissated sebaceous cysts with ? keloid change.

The acne improved, but in January 1946 two biopsies of the nodules on each shoulder showed them to be fibromata and they continued to increase in size.

The biopsy scars rapidly became keloidal, showing that the "keloidal tendency" was present.

She was referred to the plastic surgeon, who advised X-ray therapy and a course of short distance "Chaoul" therapy was tried, but, apart from slightly softening the lesions, no effect was produced. A total dose of 2,500 r, in 5 single treatments of 500 r, was used.

The lesions have remained unaffected by any form of treatment and appear to be quiescent.

Our main interest in showing this case is for prognosis and treatment.

The patient had the advantage of treatment at an early stage, when the lesions were still soft and vascular and the radiologist expected a good result.

Levitt, W. M., and Gillies, H. (1942, *Lancet* (i), 440), state that the response of keloids to X-ray therapy or a combination of X-rays with surgery is excellent in the early lesions, and this view appears to pervade the literature, especially the radiological literature, on the subject.

Several workers have suggested surgery followed by X-rays, which will have their maximal effect when the keloid tends to recur after excision, that is, from the 7th to 10th day. Some dermatologists are of opinion that it is exceptional for good results to be obtained in such cases, especially in acne keloid. The end-results may be worse than before treatment, as the keloid may be larger. One concludes that an extremely guarded prognosis should be given in these cases.

Dr. Dowling: I believe the optimistic forecast so often given in these cases to be on the whole misleading. On three occasions I have advised excision followed by radium therapy applied for the first time on the day of the operation. In each case the result has been a considerably larger keloid after the operation than before it.

Dr. Hugh Gordon: I certainly think that in this type of keloid which is long-standing, hard and resistant the best result is obtained by a combination of surgery and X-rays. The simplest procedure is excision and an X-ray exposure to the scar immediately after the operation whilst the stitches are still in situ, the optimum dose being in the nature of 800 r, the field, of course, being strictly leaded off. A more elaborate procedure, which undoubtedly gives excellent results, is for the surgeon to mark out his site of operation which is given a dose of 500 r, again strictly localized. At the end of five to six days the incision is made through the resulting erythema. A further dose of 500 r is given five to six days after the operation with the stitches in or out. This method obviously is not so simple and more time consuming.

Dr. I. Martin-Scott: I wonder why X-ray is given *before* surgical removal of the keloid. I recently had a case and went into the literature and eventually decided to remove the lesion, and Dr. Hilton of University College Hospital gave X-ray treatment (as if the keloid were still there) the week after. We considered the advantage of X-rays *after* operation was to retard the action of the fibroblasts. Why should X-rays be given *before* operation as well?

Dr. Hugh Gordon: I have never understood the rationale for the *pre-operative* X-ray, and personally have always used the alternative method.

Localized Panatrophy.—F. Ray Bettley, F.R.C.P.

A boy, aged 12.

Red areas appeared on the left buttock in September 1947, and later on the back of the thigh, which by March 1948 had become brown and shrunken. His mother says that his gait is affected and that he wears down the heel of his left shoe very quickly.

Previous history not relevant; no other complaints.

On examination.—Most of the left buttock is shrunken, subcutaneous fat having completely disappeared; there is also some loss of muscle substance. The skin over this area is irregularly pigmented and slightly atrophic, but there is no telangiectasia or redness. The skin is freely mobile over the subjacent tissues. On the back of the left thigh are two sunken areas about 3 inches across, and on the left calf two further areas; on the back of the right thigh is one sunken area. These areas are ill-defined and appear to result from a loss of subcutaneous tissue; they are not sharply punched out and the skin itself appears normal. There is objective weakness of the muscles of the left buttock.

Electrical reactions of these muscles normal. No demonstrable change in sensory or motor nerve function.

General examination normal. Blood chlorides normal. Creatinine excretion (three consecutive days) 877 mg., 734 mg., 766 mg. (normal 500 – 750 mg.). Creatine excretion 280 mg., 276 mg., 374 mg. (normal 0–200 mg.).

Histology.—Skin: The basal layer of the epidermis is pigmented. Slight lymphocytic perivascular infiltration. Fatty subcutaneous tissue absent.

Muscle: Muscle fibres are irregularly atrophic and show areas of coagulative necrosis. There is a patchy lymphocytic infiltration between the fibres.

Comment.—I have been able to find 3 other cases of similar although not quite the same sort. I was prompted to bring the patient here because of a similar case which Dr. Mitchell-Heggs and Dr. Borrie (1949) showed a year ago. Their patient was a woman who presented patches of atrophy and pigmentation; atrophy of the skin without sclerosis, and the vessels deep in the dermis and subcutis showing through the atrophic skin. There was no muscular change. There are those two differences between that case and mine, namely atrophy of the skin and no muscular change.

More like the present one was the case, the name of which I have borrowed for this patient, which was shown originally by Sir William Gowers in 1903 at the Clinical Society of London and followed up in 1939 by Barnes. That case was referred to as morphœic, intending, I think, to indicate a sharply outlined area rather than sclerosis.

Dr. Barnes kindly came and saw this boy and drew a contrast between him and his original cases and Gowers' case. In Barnes' original case, as in Mitchell-Heggs' case, there were areas of atrophic, thin, wrinkled skin with the veins showing through, again with no fibrosis; but there was degeneration and wasting of the muscle underneath the patch. Another point of distinction was the absence of pigmentation in Gowers' and Barnes' cases.

We now have three different pictures and the fourth is provided by a case of Dr. Barber's which was shown in this Section in 1932—a case of scleroderma or morphœa with atrophy of the subcutaneous tissue and muscle. I think it is clear that in that case there was a definite scleroderma, namely skin bound down to the subcutaneous tissue, but in addition to the morphœa there was a loss of subcutaneous tissue and muscle.

I present this case, therefore, as one which I have not been able to link up exactly with any of the previous cases. All show to a greater or less degree atrophy starting in the subcutaneous tissue with or without atrophy of the skin above or of the muscle beneath.

Dr. Haber: This case was under the care of Dr. Jenner several years ago. A biopsy was performed at that time and my histologic diagnosis was scleroderma.

Dr. Dowling: I suggest that this may be a case of morphœa involving the subcutaneous tissue. Similar underlying muscle atrophy in morphœa of the ordinary more superficial type is not very rare.

Psoriasis Vulgaris et Linearis.—BETHEL SOLOMONS, Jr., M.D.

Miss E. L., aged 22.

The patient states that she has had psoriasis since the age of 4, and that the linear lesion was also present then.

One brother suffers with psoriasis.

She lost her right eye when 7, due to trauma.

Examination.—General systemic examination normal. She has psoriasis of the scalp, forehead, nails of fingers and toes, and the elbow.

The linear lesion on the right leg consists of keratotic masses which stretch from a site a little medial to the fibular head, to the middle of the big toe, in an oblique line crossing near the middle of the ankle-joint. The lesion lies upon a slightly erythematous base. It scales readily. On the big toe is a well-marked punctate keratosis. W.R. and Kahn negative. Blood-count normal.

Treatment.—There has been a fair response to tar and salicylic acid.

Histology of the linear lesion was done four years ago at the Royal Staffordshire Infirmary, and was stated to be psoriasis.

Comment.—This case is presented because of the renewed interest in linear psoriasis. It may straightaway be said that many consider it to be a linear nævus.

A recent article by Auken (1949), from Lomholt's clinic, records a case extremely similar to this one in a girl aged 9. Cases of true linear psoriasis are also reported on by Stangenberg (1922), Thibièrge (1893) and Wagner (1921); Kreibich (1917) discussed its nævoid relationships. Jadassohn and Darier do not write of it.

It is of interest that in this case the lesion follows faithfully the course of the superficial peroneal nerve, and thereby fits one of the tenets of Montgomery's essentials for a linear dermatosis, of which he wrote in 1901, and which are still unaltered.

WAGNER, R. (1921) *Derm. Wschr.*, **72**, 193.

Dr. Bettley: I found it difficult to accept the linear lesion as psoriasis. I thought it was a hyperkeratotic nævus. I noticed that there was follicular plugging.

Dr. Sommerville: I looked upon it as a nævus unius lateris type of lesion and possibly the psoriasis developed on the traumatized skin of the nævus.

Dr. Sweet: She said that the psoriasis waxed and waned over the years whereas the lesion on the leg remained exactly the same, which tends to separate it from psoriasis.

Dr. Solomons: I think the latter may be a case of psoriasis superimposed on a linear nævus, but we are going to do another biopsy, if possible, and perhaps we could let you know the result. I would like to call to mind the recent writings of American authors who state that in many of their cases of clinically atypical psoriasis, biopsy is necessary for diagnosis.

The following cases were also shown :

Virilism with ? Ovarian Tumour.—Dr. L. FORMAN and Dr. W. H. MERIVALE.

Colloid Milium.—Dr. ALAN LYELL (for Dr. C. H. WHITTLE).

Eosinophilic Granuloma of the Skin.—Dr. P. FORBES BORRIE.

(These cases may be published later in the *British Journal of Dermatology*.)

Section of Anæsthetics

President—GEOFFREY ORGANE, M.D., F.F.A. R.C.S.

[*November* 4, 1949]

Change and Progress in Anæsthesia

PRESIDENT'S ADDRESS

By GEOFFREY ORGANE, M.D., F.F.A. R.C.S.

LOOKING back on the practice of anæsthetics before the last war, one realizes that there have been very considerable changes, changes as remarkable, probably, as in the previous twenty years. I wonder, sometimes, whether the rate of change we see around us is not too fast for most of us; I wonder where we are going and to what extent our journey represents progress.

The early anæsthetists devoted much of their time to work in the operating theatre. They were responsible for the formulation of anæsthetic techniques, for the development of many types of apparatus and for the investigation of a number of possible anæsthetic agents. Yet some, like Snow, found time to continue their researches into other branches of medicine; others conducted busy general practices. To-day there is a fast-growing tendency among anæsthetists to accept the confinement of their activities solely to the administration of anæsthetics. The specialist in a narrow field has, necessarily, a narrow outlook; the more he learns about, say, anæsthetics, the more he is apt to forget about general medicine. And this limitation is not at all necessary to the efficient practice of his specialty. In fact, a wide knowledge of general medicine is essential to the proper care of his patient by the anæsthetist.

It must be admitted, of course, that anæsthetic techniques have become much more complicated in recent years, and that a protracted period of training under supervision is essential if he is to become expert in administration. From the open mask and the Clover, with their rather limited range of possibilities, we have progressed to anæsthetic machines, streamlined and chrome-plated or stove-enamelled in pastel hues, whose powers of destruction in the hands of the half-instructed are as considerable as their powers for good when properly handled. We must be experts in intravenous, intrasternal, spinal, epidural and local anæsthesia: we must be laryngologists, tracheologists and bronchologists, and we must have something of the miraculous powers of guardian angels if we are to protect our patients against the onslaughts of some of the more radical surgeons.

To this extent the general practitioner is handicapped, that he cannot hope to master these technicalities by himself. To take one example, that of anæsthesia for intrathoracic operations: the recent developments in surgery have been made possible by the advances in anæsthesia; but these advances are not the result of one man's work, nor could they be: they are the result of the combined experience of many men over a long period. The relative isolation of general practice makes it difficult to keep up with the advancing tide of common experience, but I see no reason why, *if he is already fully trained*, he should not be able to keep himself up to date.

Let us assume, however, that we are to become anæsthetists, debarred from practising any other branch of medicine. We cannot be expected to spend the whole of our working time in the operating theatre. It would be as unreasonable as to expect surgeons to subdivide themselves into clinical and operating. We must have other interests to occupy a part of our time.

Logically, these interests should extend from the duties we undertake in the operating theatre. Our medico-legal colleagues hold that we are responsible, in law, for the pre-operative assessment of the patient's general condition and fitness for operation, for the selection of the appropriate premedication, for the choice of anæsthetic agent and technique, and for the care of the patient's health during the operation and during the immediate post-operative period, until recovery from the anæsthetic can be said to be complete. That is our duty—and our right; but we must be reasonable. Good surgery depends on good team work, which cannot exist without mutual confidence and respect. A team cannot be built from a number of individuals, however brilliant, who insist on pulling in opposite directions. We can best establish our position in the surgical team, not by an arrogant insistence on our rights, nor by extolling our virtues but, in the first instance, by demonstrating our ability to give a good anæsthetic, which, we are sometimes inclined to forget, is the prime reason for our existence. The rest will follow: most surgeons will tell you that they are only too happy to be able to leave everything to the anæsthetist, so that they may concentrate on the operation; but this implies an anæsthetic so unobtrusively good that the surgeon can forget about it.

Pre-operative Examination and Preparation of Patients

It still happens that the surgeon will call upon a physician, in a doubtful case, to decide upon the patient's fitness for operation. It can be very irritating to be told, the night before, that a patient has been seen by the physician, who has pronounced him "fit for a general anæsthetic". Such a vague opinion is of no value to us, and can absolve us of none of our legal responsibility to the patient. Fit for what general anæsthetic and, more important, by what anæsthetist? On the other hand, there are many cases in which we should be glad to have the advice of someone more expert than ourselves. The physician can best help us by recording his findings, and his interpretations thereof, which can guide us in our choice of anæsthetic agent and technique. Ideally, the physician, surgeon and anæsthetist will meet in consultation on any doubtful case, to discuss the problems involved. This practice already obtains in some centres and I have no doubt that it will be more generally adopted. Such discussions can do us anæsthetists nothing but good—and dare I suggest that the benefit could be mutual?

For many relatively trivial procedures the pre-operative condition of the patient is not of great importance; provided, always, that we treat him to the best of our knowledge and ability. It is often difficult for us to visit our patients beforehand, particularly when we first hear of their existence late in the evening before operation, and we often leave the pre-operative examination to a junior house surgeon or house anæsthetist. While this is far from ideal, it is generally adequate; but what are we to do when we are confronted with a patient who, we discover, has certain complications which we know are likely to reduce his chances of recovery from a major operation? With the present shortage of surgical beds, we may be reluctant to insist on the postponement of operation that we know is right. We believe that dirty teeth increase the chances of post-operative chest complications; we know that these are at least five times more common in heavy smokers than in non-smokers; we know that the chronic bronchitic should be kept under observation to ensure that he is at his best when he comes up for operation; we know that many patients with heart disease will benefit from a period of rest in bed, perhaps with digitalization; we know that immediate pre-operative transfusion is not adequate treatment for chronic anæmia with its accompanying myocardial changes.

The logical solution to this problem, as is often the case, has been reached simultaneously in more than one part of the world. While many of us have toyed with the idea, the Pre-operative Out-patient Clinic has been established. Mendez Peñate has one in Cuba; there is another in Southend [1].

There is nothing extravagant in this suggestion which, I believe, can do nothing but good. The patient could be examined at leisure; any necessary biochemical, pathological or radiological investigations could be completed, dental toilet could be undertaken, difficult cases or diabetics could be referred to the physician; the heavy smoker or the alcoholic could be frightened, at least into a reduction of his consumption, in time for real benefit to be gained. Where a period of rest in bed was considered desirable, this could be undertaken either in the patient's home or in a convalescent home—an institution much better adapted to pre-operative than to post-operative care. On admission of the patient to hospital, the anæsthetist in charge of the case would have access to the out-patient notes and would be advised which of his patients he should, himself, visit before operation.

Such an arrangement would seem to cover most deficiencies with the least inconvenience to the anæsthetist and with considerable advantage to a hospital that has to fit an appalling number of urgent cases into a totally inadequate complement of surgical beds.

Resuscitation and Oxygen Therapy

The anæsthetist is no longer the chloroformist but the man who keeps the patient alive in the operating theatre. This change in the conception of his duties began many more than ten years ago but it is only recently that it has been generally recognized. With the widespread adoption of the practice of keeping detailed records of the progress of the patient in major operations, the anæsthetist has become better able to interpret his findings —though we still find many reactions that pass our comprehension. I have no doubt that, as things are, the anæsthetist is the best placed in the operating theatre to decide upon and to supervise resuscitative measures.

As the anæsthetist is the resuscitation officer in the operating theatre, he could, usefully, become the resuscitation officer to the hospital as a whole with overall clinical charge of blood transfusion and all forms of intravenous therapy. This is not to suggest that the anæsthetist is, *ipso facto*, qualified to become resuscitation officer. Most of us have a fair working knowledge of the subject but our theoretical background is often woefully inadequate. Our training in these matters falls a long way behind that provided in many American and Canadian centres. The resuscitation officer should be as fully informed as any of his medical and surgical colleagues on all aspects of his work, if he is to be of real value to them. The task is beset with pitfalls and would require the closest and most tactful co-operation with physicians, surgeons and pathologists.

The anæsthetist who is also the resuscitation officer would include among his duties the supervision of oxygen therapy and the maintenance of apparatus. The need for such supervision will become apparent on inspection of the wards of any of our great teaching hospitals. The anæsthetist is the only member of the staff who is likely to be thoroughly familiar with the workings of the apparatus; from his duties in the theatre he understands the control of airway from the lips to the bronchioles and he is, or should be, an authority on all forms of artificial respiration.

I am convinced that we shall have to establish recovery beds where patients can be tended by experienced nursing staff in the early post-operative period, and I am also convinced that such beds are best placed in the charge of the anæsthetist. We are all aware of the dangers attendant upon the return of the patient, supervised by a theatre porter and a probationer nurse, to a ward where the harassed and overworked nursing staff, towards the end of a long operating list, have to combine their supervision of unconscious and sometimes gravely ill patients with the distribution of lunches or the issue of bed pans! Recovery beds may be placed near the operating theatre where they can be visited at frequent intervals by the anæsthetist in charge, who is immediately available in case of necessity. Harold Griffith [2] lists the advantages as follows :

Patients receive expert and immediate care during the critical period of recovery from anæsthesia and operation.

All emergency equipment is available and kept in good condition. Floor nurses are saved time and worry, since the patients are not returned to the wards until they are conscious and in fairly good condition. Student nurses are given supervised instruction in the immediate post-operative care of patients. The recovery room may be used as an emergency ward for the treatment of shock or unconsciousness from any cause.

The average stay of patients in Griffith's recovery room is less than one hour. Most hospitals could more easily provide a recovery ward situated in some other part of the building than the theatre block, where patients might remain for the first twenty-four hours. Such segregation would be a boon to the inhabitants of the surgical wards who were in the pre-operative or the convalescent phase of their treatment.

Treatment of Post-operative Complications

As the anæsthetist is responsible for pre-operative assessment of the patient and for his care during the operation, it is not unreasonable that he should take an interest in the treatment of such post-operative complications as are not, by their nature, the direct responsibility of the surgeon—notably the post-operative pulmonary complications. Many of us have had the opportunity of treating such complications, but only sporadically. That we do not do so more regularly is, I think, largely our own fault. If we were more assiduous in our post-operative follow-up of our patients, we would more often be the first to diagnose such complications; from this it is an easy step to secure the surgeon's agreement to our taking part in the treatment.

I have touched on some directions in which we can extend our activities with benefit, I think, to all concerned. The management of the pre-operative out-patient clinic, the charge of the resuscitation ward, of blood transfusion, intravenous therapy and oxygen therapy, a share in the care of the patient after operation, the performance of therapeutic and diagnostic nerve blocks, of bronchograms and of arteriograms, with the occasional

administration of an anæsthetic, should provide fare to satisfy the appetite of the most avid anæsthesiologist!

Developments of Anæsthetic Technique

One of the most impressive changes, to my mind, of the past ten years, has been the appearance of large numbers of anæsthetists whose knowledge and technical skill approach that of the best of the pre-war years.

A dramatic change came with the provision, through the E.M.S., of a reasonably efficient anæsthetic machine in every hospital in the country. We have enough trained anæsthetists who are capable of displaying the undoubted advantages that can be derived from these machines; but it is still not sufficiently widely appreciated by hospital authorities that they are potentially dangerous, and we hear, from time to time, of tragedies arising from their improper use by the ill-instructed. They would be safer if fitted with non-interchangeable couplings, but, as these couplings extend only from the regulators to the flowmeters, they may be a snare and a delusion while it remains possible to connect the wrong cylinders to the regulators. Two deaths occurred during the use of a machine of recent design which is foolproof except in this one respect and which may, therefore, have lulled the anæsthetists into a false sense of security.

We have seen the widespread adoption of the carbon dioxide absorption technique and of the use of cyclopropane, which was little more than a name to the majority of anæsthetists ten years ago. Our first enthusiasm for cyclopropane has waned and we now appreciate that there are occasions when ether is preferable.

Our attitude towards apnœa during anæsthesia has changed in a remarkable way. It is to-day only a minor incident in those cases in which it is not produced deliberately in the establishment of controlled respiration. This latter is now a valuable part of our armamentarium though I feel that many who employ it do not fully understand the dangers of under-ventilation with an accumulation of carbon dioxide: the terms cyclopropane shock and curare shock have been added to our vocabulary.

Waters has undertaken an assessment *de novo* of chloroform and we await with interest his final verdict. I have held for some time that if chloroform were a new discovery, used sparingly as an adjuvant to nitrous oxide and oxygen, we should hail it as a great improvement on all existing anæsthetic agents.

We have been introduced to trichlorethylene. The pendulum of favour has swung more than once and has not yet come to rest. There have been deaths associated with its use in anæsthesia but usually, I think, where there has been an incomplete appreciation of its limitations. I value it chiefly for its truly impressive analgesic properties; used intelligently for the production of analgesia it is probably completely safe, and I feel that it is for this purpose, in the main, that we shall retain it in our armamentarium.

Encouraging tales of new ethers are coming from the United States but we have, so far, little experience of them in this Country. Though we understand their limitations and disadvantages, most of us still rely, largely, on nitrous oxide and ethyl ether, which have survived more than a century of clinical trial. Our efforts to overcome their limitations and to reduce their disadvantages have produced the most dramatic development of recent years—the introduction into anæsthetic practice of extracts of curare. Though *d*-tubocurarine chloride has been widely used for some years and has been freely discussed at meetings of this Section we cannot yet claim to have mastered it [4, 5, 6]. Some of us have seen bronchospasm and massive collapse of the lungs, others have been more fortunate. These complications have been attributed to the release of histamine, but I understand that, with the doses of tubocurarine usually employed, the amount of histamine released is too small to have an effect except on the hypersensitive patient. It could be that these patients have been hypersensitive to histamine, and it is a subject that would repay investigation; but I think the ill-effects are more probably associated with variations in anæsthetic technique. The position is complicated by the fact that we are now enabled to provide satisfactory operating conditions at a much lighter level of general anæsthesia than was previously possible. At such a level of anæsthesia we should expect to see reactions we have not seen before and I feel that this, rather than any inherent fault of tubocurarine, is responsible. So far as I have been able to follow these cases, it appears that they are associated with the presence of a tracheal tube—a potential source of reflex disturbances—in light anæsthesia from thiopentone and cyclopropane, both drugs that tend to enhance the activity of the parasympathetic nervous system. In our present state of knowledge of tubocurarine I feel we would be wise to avoid tracheal intubation where we can safely do so: to maintain true surgical anæsthesia, preferably, in the lower first plane: and to use ether, which we know to be a bronchodilator, as our main anæsthetic agent.

There are now a number of substitutes for *d*-tubocurarine some of which, we feel, may have been placed on the market without sufficiently full investigation. Myanesin has been

fully discussed in this Section [3] and most of us feel that, in its present form, it is not suitable for use in anæsthesia. Flaxedil is effective and its use has, so far, disclosed no important disadvantages. Decamethonium is effective and is, perhaps, better than the others for oral endoscopies and for such operations as appendicectomy because of its shorter action. Unfortunately, with compounds having a relatively small molecular weight, the potency of a given weight of the salt varies inversely with the weight of the attached halide radical. Here we use decamethonium iodide; in the United States one firm markets the much more active bromide; another marks on the label the weight of the decamethonium radical! We are promised more synthetic muscle relaxants, and new alkaloids of curare are on the way. I would like to see all such drugs labelled in terms of their relative potency to the standard, *d*-tubocurarine chloride. The prospects of confusion are, otherwise, appalling.

Though basal narcosis, in the sense of pre-anæsthetic unconsciousness, is almost universally practised, we have seen the virtual abandonment of avertin and the widespread adoption of thiopentone.

We have some new tubes, but there have been no changes in the principles or practice of tracheal intubation except the introduction of Macintosh's curved laryngoscope blade. Though views as to the general applicability of this will vary, there can be no doubt of its value in certain cases. Tracheal intubation is now more widely and, in my opinion, too light-heartedly practised. There are many clear-cut indications for intubation; but it does represent a potential source of additional trauma to the patient and should not be used without good reason. There is a movement, with which Magill has associated himself, towards preference for orotracheal to nasotracheal intubation on the grounds that it permits the employment of a larger tube. While a tube the size of the trachea may be essential to an athlete running a race, a very much smaller one is large enough for a patient breathing quietly under anæsthesia: and I feel that Magill's blind nasal intubation is less often injurious than the laryngoscopy that usually accompanies orotracheal intubation.

New problems, which have been introduced by thoracic surgeons, have been overcome by use of the already established techniques of bronchial intubation and bronchial blocking with or without suction. These manipulations are difficult, not always successful and often traumatic. There is an increasing tendency to use tracheal intubation alone, with postural drainage of "wet" cases in the prone rather than in Beecher's original lateral position.

The last ten years have seen the introduction of the continuous spinal and continuous epidural techniques, but these are not yet widely used in this country.

There has been, however, a widespread revival of interest in local and regional blocks though we are still a long way behind the standard of knowledge and practice to be found in the U.S.A. and Canada. This was brought home to me by a particularly effective demonstration in the nerve block clinic of a French hospital in Montreal. The only new technique that has appeared here recently is the vagus nerve block of Macintosh and Mushin.

A novel practice is the attempt to control hæmorrhage by a deliberate lowering of blood pressure with Gillies' total spinal block (7) or by partial exsanguination through an arterial cannula, controlled with auto-transfusion. Scurr has recently achieved this effect by injection of pentamethonium iodide, a substance with a similar action to tetra-ethyl-ammonium iodide. Though there are a few operations where bleeding *must* be minimized, the widespread adoption of this principle will, surely, lead to frequent reactionary hæmorrhage.

Anæsthetic Records

The recognition of our imperfections has produced a greater interest in the search for better methods of anæsthesia. Few of us have opportunities for pharmacological or physiological research, none comparable with those available at some centres in America. The use of anæsthetic records, usually on Nosworthy's card, is now general. Such records are of great value in focusing the attention of the anæsthetist on any oddities in his patient's behaviour and will help to draw attention to such oddities as recur from time to time. It is unwise, however, to attempt to draw more than limited conclusions from these: it is not possible to record in detail everything that happens to every patient before, during and after operation. A line of investigation, suggested by inspection of routine records, must be carefully planned if it is to lead to reliable results with a reasonable economy of time and material. We have become aware of the value of statistics and we now realize that much painstaking work, on the conclusions drawn from which some of our practice is based, is completely valueless and must be repeated. Yet a statistical analysis is no better than the data on which it is based: with so many potential variables, careful and critical observation is the first essential.

The question of deaths under anæsthesia has always been a matter of concern to us and we are disturbed at the large number that we feel are avoidable. Chloroform fell into disrepute because of its dangers; from such figures as we have, it seems that thiopentone is much more lethal though the fault lies, probably, in the method of use. No one anæsthetist is likely to have a sufficient experience to be able to draw conclusions for the guidance of his fellows. We hope much from the investigation recently started by the Association of Anæsthetists.

The future affords unlimited opportunities for interesting, stimulating and extremely satisfying work. We are aware of the deficiencies of our handling of the agents available to us. The ideal anæsthetic agent has yet to be discovered—it may be that the pananæsthetic will prove as elusive as the panacea. For the present we can do best by using a judicious combination of anæsthetics and adjuvants. In 1938 I was accused of practising polypharmacy—nowadays we call it balanced anæsthesia. But I would urge the younger anæsthetists to realize that it is impossible to handle satisfactorily these complicated mixtures until one has mastered the use of the separate ingredients. In recent years we have made anæsthesia infinitely more pleasant for the patient and we have made notable advances towards the provision of ideal operating conditions for the surgeon. We have not made anæsthesia safer, and until we have done so we cannot be satisfied.

Effects of Faulty Posture

PRESIDENT'S ADDRESS

By H. A. BURT, M.B., B.Chir., M.R.C.P.

LITTLE attention has been directed in recent years to the relation between disturbances of posture and disorders of the locomotor system. This is largely to be accounted for by the recognition of the prolapsed intervertebral disc and its clinical implications. Another contributory factor is that the standard of postural treatment is often inadequate, in consequence of which results of treatment are poor. It can readily be appreciated that belief in the importance of postural treatment is likely to diminish if patients, for whom such treatment is prescribed, repeatedly fail to make symptomatic or structural improvement.

In what may be called the orthopædic era of low back and sciatic pain, when lumbosacral and sacro-iliac strains were considered the most important causes of these disorders, attention was naturally directed to the mechanics of the back. Between 1929 and 1939 numerous papers on posture appeared in the medical literature; the White House Committee on "Body Mechanics" reported in 1934, and the first two editions of the celebrated book by Goldthwait, Brown, Swaim and Kuhns appeared in 1934 and 1937. Now that the prolapsed intervertebral disc is held—almost certainly correctly—to be the most important cause of sciatic pain, and is also considered by some—almost certainly incorrectly—to be the most important cause of low back pain, interest in the mechanics of the back has diminished and contributions in the English and American literature are few and far between.

In this lecture three arguments will be developed; first, that notwithstanding the prolapsed intervertebral disc, there is a significant relationship between faulty posture and low back pain; second, that pain in the limbs and in other parts of the back are often to be attributed to postural defects and, third, that corrective postural treatment carefully worked out and purposefully carried out, greatly benefits a large group of patients attending Departments of Orthopædics and Physical Medicine.

NORMAL POSTURE

Posture can be regarded from the different viewpoints of the physical educationalist, who is chiefly interested in form; the anatomist, who is chiefly interested in structure, and the clinician whose main interest lies in the relation of posture to disease. Opinion of what constitutes good posture has undergone many changes in the course of time, and in the past has often been influenced by æsthetic and utilitarian considerations. The Greek idea of good

posture can be judged by studying their statues; it embodies the characteristics of the supreme athlete who in those times was an all-rounder. It might be thought nowadays when athletics are increasingly popular that we should return to the Greek ideal of posture. We find, however, that there are no special postural features characteristic of the athlete. Rather is there marked lack of uniformity, some athletes in the highest class showing postural defects of the back and even of the feet.

In the past, physical educationalists exerted an important influence. We find, for example, that it was they who encouraged the lumbar lordosis and prominent chest which was particularly common in Germany, and also in the Sergeant Majors of most countries. This posture was encouraged as it gave the impression of domination and strength. Not many years ago a reaction set in against the lordotic stance and people were encouraged to develop the flat back, which, as Wiles (1937) and others have shown, is not infrequently associated with low back pain. The extent to which physical educationalists have been prepared to go is shown in the following statement from a book of gymnastics quoted by Appleton (1946). "In women the shoulders should not be drawn back as this would appear unbecoming and defiant." The æsthetic and utilitarian aspects will evidently not carry us very far.

From the point of view of anatomy, no rigid rules can be laid down owing to the large variation in the physique of members of a community. Those who are familiar with Sheldon's classification (1940), and study his illustrations (Fig. 1, A, B, C) of extreme ectomorphy, mesomorphy and endomorphy will appreciate the need for a wide definition.

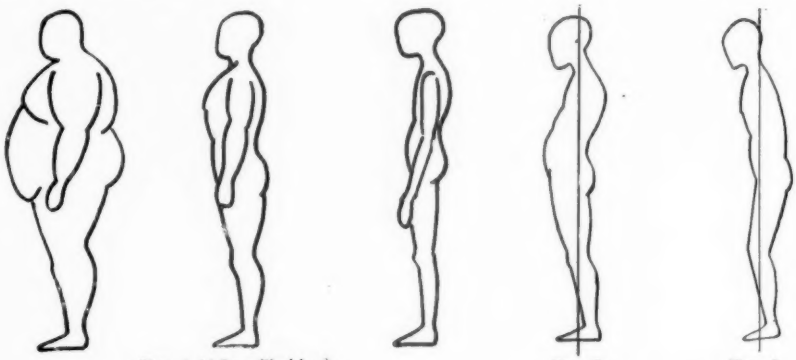

FIG. 1 (After Sheldon).

(A) Extreme ectomorphy.

(B) Extreme mesomorphy.

(C) Extreme endomorphy.

FIG. 2. Forward carriage of pelvis. Compensatory backward sway. Gluteal cleft in front of heel.

FIG. 3. Backward carriage of pelvis. Compensatory forward sway. Gluteal cleft behind heel. Flexion of knees.

Certain rough tests are of considerable help to the clinician. The first of these is to suspend a plumb line from the tip of the mastoid process. The plumb line should pass through the greater tuberosity of the humerus, the great trochanter of the femur, and through a point about $1\frac{1}{2}$ inches in front of the lateral malleolus. The last point is at the level of the tuberosity of the tarsal scaphoid. The plumb line will not pass through all these points if, the chin is poked forward, the shoulders are rounded, or if there is forward or backward carriage of pelvis.

The next rough test is to observe the pelvic carriage, the significance of which has repeatedly been emphasized by Appleton (1944, 1946, 1949). Normally the upper end of the cleft of the buttocks is approximately in the same vertical level as the back of the heel. With a forward pelvic carriage (Fig. 2) the ankle is dorsiflexed and the pelvis is over the front instead of the back of the foot. To restore balance of the body which is thereby disturbed adjustments in the back have to be made, the commonest of which is a backward sway in the dorsilumbar spine. Less frequently except in pregnant women (Appleton, 1944) there is backward carriage of the pelvis, the essential feature of which is flexion at the knee. To compensate disturbance of balance the trunk comes forward (Fig. 3) and a posture described by Wiles (1937) as "Round Back Type I" is produced.

The pelvic carriage is measured by observing the position of the intergluteal cleft relative to the back of the heel, the permissive range lying between 2 inches in front and ½ inch behind (Appleton).

Neither of the two tests described above provides any indication of the curves of the spine. The lumbar region is most conveniently studied by the measurement of the pelvic angle for which purpose Wiles devised a special inclinometer. The two points advised by Wiles are the upper part of the symphysis pubis in front and the posterior superior iliac spine behind. Appleton prefers the anterior superior iliac spine to the symphysis but also uses the posterior superior spine. The normal angle with Wiles's points is about 30 degrees, with Appleton's 5–10 degrees, an increased angle denoting a lumbar lordosis, a decrease denoting a flat back.

The cervical and dorsal curves are judged by noting respectively the relation of the back of the head and the most prominent part of the dorsal spine to the gluteal cleft. A cervical kyphosis is present if the occiput is more than 2 inches in front of the cleft, a lordosis if the back of the head is over half an inch behind. The dorsal curve may be considered abnormal if its more prominent part is over half an inch behind the gluteal cleft.

Types of Faulty Posture

(1) *Lumbar lordosis.*—Though lumbar lordosis is an important variety of faulty posture, the impression often given that it is the most important and most common postural fault is untrue. The features are as follows, there is an increase of the pelvic angle, overaction and later shortening of the erector spinæ and hip flexors, and weakness and stretching of the glutei. Often the abdominal muscles are also stretched and weak, but this, contrary to the general opinion, is not invariable. Moreover, as Wiles has pointed out, contraction of the abdominal muscles unaccompanied by contraction of the glutei has no effect in tilting the pelvis, and therefore no effect in correcting lordosis. That is not to say that poor abdominal musculature may be ignored, for clearly with a protuberant abdomen and consequent displacement of the abdominal organs the centre of gravity of the body is altered and needs correction.

Fig. 4.
Shop-girl's hip. L. buttock protruding. Weak and stretched L. gluteus medius. R. knee bent.

Sway back. Type I. (Wiles's round back Type II).

Sway back. Type II. (Wiles's sway back)

Common features: Tight pectoral muscles; weak rhomboids; forward carriage of pelvis; weak abdominal muscles.

Differences: Decreased or normal pelvic tilt (Type I); Increased pelvic tilt (Type II).

Fig. 5.

(2) *Shop-girl's hip.*—The term "shop-girl's hip" was used by Wesson (1938) to describe a relatively common postural fault in which the subject habitually stands with one knee bent, and the opposite buttock pushed out. This results in stretching and weakness of the gluteus medius and sometimes the Trendelenburg test is positive. Clinically patients with "shop-girl's hip" may present in one of three ways, with postural backache, with "swelling of the hip", with pain referred to the abdomen which, if on the right side, is often diagnosed as appendicitis. There have been innumerable instances of removal of a normal appendix when what was required was a course of postural exercises, and at least one patient had an unnecessary exploration for a tumour of the buttock.

(3) *Flat back*.—The term "flat back" is self-explanatory. The condition as a rule occurs in young women and gives rise to backache which is often resistant to treatment.

(4) *Sway back*.—The most common type of faulty posture encountered at the present time is the "sway back". There are two variations of the fault, and this often gives rise to confusion in terminology. It should be realized that the essential feature of both varieties is the same, namely a forward carriage of the pelvis. The difference between the two lies in the pelvic inclination. In Type I, which in my experience is the more common, there is no increase in the pelvic angle (there may even be a slight decrease), and the sway starts in the mid or upper lumbar region. In the less common Type II there is an increase of pelvic inclination and the sway begins at the lumbo-sacral junction. In both types of sway back other features are usually present, namely weakness of the abdominal muscles, tightness of the pectorals and poking forward of the chin.

In his classification of posture Wiles restricts the term sway back to the second type; for the first he uses the term "Round Back Type II".

(5) *Dorsal kyphosis*.—According to Wiles dorsal kyphosis usually follows dorsal epiphysitis (Scheuermann's disease), and Windle (1945) also found that a large proportion of young soldiers with dorsal kyphosis attending the Army Physical Development Centres showed evidence of epiphysitis. Dorsal kyphosis is also a common finding in middle-aged chronic bronchitics. The postural fault is invariably accompanied by rounding of the shoulders, tight pectorals and poor rhomboids.

(6) *Poking chin*.—The last type of deformity to be discussed is "Poking Chin" (Fig. 6). The features are as follows: there is an obliteration of the cervical lordosis and a compensatory tilting back of the head at the atlanto-occipital joint. In the posterior cervical muscles there is stretching and weakness of semispinalis cervicis and overaction with ultimate shortening of semispinalis capitis. The corresponding flexor muscles in front, namely, longus cervicis and longus capitis shorten and lengthen respectively. In middle-aged women in whom this postural fault is relatively common, a pad of fat over the seventh cervical and first dorsal spines may develop, to which the name of "the dowager's hump" is sometimes given.

Head tilted back at atlanto-occipital joint.
Chin forward.
Decreased cervical lordosis.
Stretching and weakness of semispinalis cervicis and longus capitis.
Shortening of semispinalis capitis and longus cervicis.

FIG. 6.—Poking chin.

FINDINGS ASSOCIATED WITH FAULTY POSTURE

There are certain findings associated with faulty posture which occur so frequently, and which often appear to play such an important part in the production of symptoms that it seems reasonable to ask if it is the postural fault with which we should primarily be concerned, or a collection of findings of which the anatomical defect is one. Are we, in fact, really dealing with a syndrome of faulty posture? Associated findings are three in number and consist of inability to relax muscles, diminished agility, and limitation of movement of the spine.

Incomplete muscular relaxation, often over a wide area, is present in the majority of patients with long-standing pain in the back. It is often described as muscular spasm and is regarded as a protective mechanism. That protective muscle spasm does occur cannot be denied, but it is usually in response to acute pain. The "spasm" under consideration occurs when pain is not acute; it may affect single or multiple groups of muscles. An example of incomplete relaxation in a single muscle group is seen in patients with chronic lumbar pain. When such patients lie comfortably on a couch in the prone position, even under a heat lamp, the erector spinæ remain tense even though no pain is experienced at the time. Prolonged treatment may be necessary before such patients are able to relax their muscles, but when the habit of relaxation has been re-acquired symptoms almost immediately start to improve. Until then, however, progress is slow. An example where many groups of muscles are involved is seen in long-standing acroparæsthesia, where the head, neck and shoulders are held tensely and the muscles of the arm and forearm are tight. The latter may be the predisposing cause of pain in the elbow which not infrequently complicates acroparæsthesia.

Inability to relax muscles produces or increases fatigue muscle pain; it also ultimately leads to muscular wasting, for a muscle which never fully relaxes never fully contracts, and a prolonged period of incomplete muscular contraction is followed by wasting.

Lack of agility and movement may be considered together. There are two chief causes, first, incomplete muscular relaxation described above, and second, the result of adhesions either between the muscle fibres or between muscle groups. These adhesions which were described by Gratz (1937) interfere with normal contraction of muscle and also with the gliding of one muscle over another.

When abnormal posture has been maintained for a long time shortening occurs in muscles, ligaments and joint capsules, and in severe cases there may be alteration in the shape of the vertebræ. In these instances full correction by non-surgical methods is out of the question.

Clinical Sequels of Faulty Posture

The clinical conditions associated with faulty posture may conveniently be considered under three headings. Fatigue muscular pains in any part of the back constitute a primary group, acroparæsthesia, back strain and chronic recurrent cervical fibrositis constitute a secondary group, and osteo-arthritis of the hip and lumbar spine a late secondary group.

Primary Effects

In a Department of Physical Medicine patients are frequently seen with a history of pain in one or other region of the back which develops during the day, is made worse by long periods of standing and is relieved by rest. The pain is of a dull aching character; it is never acute or stabbing, and after a night's rest the back feels entirely normal. As time goes on the aching pain develops earlier in the day, but for months, and often for years, the response to rest is unchanged.

Muscle fatigue is the probable explanation for these symptoms. Its cause is that either the muscles are too weak for prolonged use, or that they are playing too great a part in the maintenance of the upright posture. The backache associated with a flat back is an example of pain arising from a muscle which is too weak. The pain occurring with a lumbar lordosis is an example of a muscle having too much to do, for with lumbar lordosis the upright posture instead of being maintained by equal action of the erector spinæ and glutei is maintained by the erector spinæ alone.

Secondary Effects

A. Acroparæsthesia.—A great increase in the incidence of acroparaesthesia has been noted by many. The symptoms consist of pain down the arm, numbness and tingling in the hands of both sides, nearly always worse at night and first thing in the morning. Throughout the night the victim is awakened by "pins and needles" in the fingers and in the morning the arms ache and the fingers are clumsy, so that it is difficult to pick up a cup of tea and not infrequently the cup is dropped. Such activities as carrying baskets and ironing clothes invariably aggravate the condition which affects members of the female sex almost exclusively, the victim as a rule being a middle-aged woman. On clinical examination abnormal physical signs are absent with the exception of horizontal clavicles and some drooping of the shoulders.

For many years the condition was diagnosed as brachial neuritis. The opinion has recently been put forward by Walshe, Harvey Jackson and Wyburn Mason (1944), that acroparæsthesia is due to an altered relation of the shoulder girdle and thoracic outlet secondary to poor tone of the shoulder girdle muscles. Traction and compression of the lower cord of the brachial plexus and possibly also the subclavian artery are the essential mechanical factors underlying most, if not all, cases of acroparæsthesia in women.

Walshe's (1945) clinical description of acroparæsthesia cannot be improved upon. His remarks on treatment, however, require some qualification: "Treatment" he writes, "is generally allowed to be unsatisfactory and includes radiant heat, massage, ionization and diathermy and when the desperate patient has sought relief from practitioners not on the Medical Register, manipulation of the spine is still further added to her torments." If acroparæsthesia is in fact caused by sagging of the shoulder girdles, radiant heat, massage, ionization, diathermy and manipulation cannot be expected to have any effect. The only logical method of treatment is to correct the sagging of the shoulders by improving the tone and strength of the shoulder elevator muscles. This is borne out by results when treatment along these lines is carried out.

B. Back strain.—A common cause of acute back pain is a tear of a muscle, joint capsule or ligament. Such a tear or "strain" is likely to occur at the junction between elastic and less elastic tissues, or between elastic and non-elastic tissues (Cohen, 1948), a common site being the attachment of muscle or ligament to bone. For example, it occurs in the back where the muscles are attached to the transverse processes of the vertebræ, and also where the inter-spinous ligaments are attached to the spines. The reason why strains are particularly common in subjects of faulty posture is because of their lack of agility and limitation of movement. The normal, mobile back can adapt itself to sudden and unexpected movements. The back moves quickly and there is a large range over which the spine can move without over-stretching muscles or ligaments. The spine which is not agile cannot react quickly to the unexpected, and a clumsy, abnormal movement is made. Moreover, if there is also shortening of muscles and ligaments, a sudden or relatively large movement is likely to cause a tear. There was a great increase in the incidence of back strain in the earlier part of the war when middle-aged and elderly gentlemen, who were quite unused to exercise, took to gardening. In the majority of instances the spine was found to move slowly, movement was often limited and posture abnormal.

C. Chronic recurrent cervical fibrositis.—Though not, strictly speaking, a direct consequence of faulty posture, chronic recurrent cervical fibrositis may be considered here owing to the frequency with which it is found in association with "poking chin". Many patients give a history of having received repeated courses of heat, massage and other forms of physio-therapy. Often relief has been obtained, but, as a rule, it has been partial and temporary. A great difference can often be made to these unfortunate people if, in addition to physio-therapy given to relieve pain, the postural defect is also attended to.

It is not suggested here that all cervical fibrositis is due to bad posture. It is, however, pointed out that fibrositis and bad posture are commonly associated, that faulty posture is undoubtedly an aggravating feature and that it may also be an important predisposing cause.

Late Secondary Effects

A. Osteo-arthritis of the hip.—Osteo-arthritis is likely to occur in joints whose mechanics have been seriously disturbed, whether by disease, deformity or trauma. The association of faulty body mechanics and osteo-arthritis of the hip has been emphasized by Kuhns on more than one occasion (1934, 1942). Normally at the hip-joint the weight of the body is borne by the central portion of the femoral head in contact with the strong upper portion of the acetabulum. Whenever this is not the position of use, as is the case when an increased forward inclination of the pelvis accompanies faulty body mechanics, disalignment results and osteo-arthritis is likely to occur.

Kuhns (1942) treated a series of 183 patients with osteo-arthritis of the hip by conservative rather than surgical treatment. The aim of treatment was to restore normal weight bearing as much as possible, and this was achieved with exercises concentrated on correcting the lumbar lordosis and improving the tone of the glutei. Where necessary patients were fitted with a low back support. The end-results of treatment were striking. Of the 158 patients who were followed up 47, including 28 with bilateral osteo-arthritis, returned to work free from symptoms, and another 58 had slight symptoms only. Important points raised by Kuhns are, therefore, first, that there appears to be a significant relation between faulty posture and osteo-arthritis of the hip, and second, that attention to body mechanics is likely to have beneficial results on osteo-arthritic patients.

With regard to ankylosing spondylitis Swaim (1949) states first, that in spondylitic patients whose posture is good, hip involvement is rare; second, that if attention is paid to posture in the early stages of the disease, hip involvement can usually be avoided; finally, he quotes instances of spondylitics with hip involvement where great improvement of hip function resulted from correction of faulty posture.

Treatment

There is perhaps no form of physiotherapy which requires more accurate performance than the correction of faulty posture. Minor errors of judgment are likely to have serious effects on the result of treatment and may nullify it altogether.

In the treatment of faulty posture five factors have to be considered: improvement of agility, improvement of mobility, re-acquisition of the ability to relax muscles, improvement in the strength of weak or relatively weak muscles and finally re-education of the postural reflex, that is to say, the patient must be taught automatically to adopt the correct posture

and to maintain it in all circumstances. In planning treatment it is necessary to assess these five factors for each individual and list them in order of priority, for it must be realized that their relative importance varies from patient to patient. For example the most important factor with a flat back is that the muscles are weak, and in such a case the emphasis must be laid on improving their strength. In the sway back re-education of the postural reflex is the most important factor. With a dorsal kyphosis it is usually lack of mobility which must be dealt with before symptomatic improvement will be obtained, while in many instances of lumbar pain associated with a lordosis an essential condition of improvement is the ability to relax the erector spinæ muscles.

Improvement of agility is best achieved with exercises in a class. The methods of obtaining improvement of mobility vary according to whether limitation is due to intermuscular adhesions, tightness of ligaments or shortening of muscles. Mobilizing exercises, in some instances supplemented with massage or faradism, may be expected to improve the first group. When there is tightness of ligaments, traction, continuous in severe cases, repeated in the less severe, is the method of choice, a halter being of value with lesions in the cervical and upper and mid-dorsal regions (Wiles). When there is muscular shortening care has to be exercised for it is generally agreed that forcible stretching of muscles is undesirable and may be dangerous. Wiles and others recommend that exercises against resistance for the antagonists produce complete relaxation of the shortened agonist muscles and ultimately lead to increase in their length.

Individual treatment is necessary in the early stages to teach muscular relaxation and also to re-establish a normal postural reflex. To start with individual treatment is also necessary for the teaching of specific muscle strengthening exercises. When these have been mastered the patient should join the class.

Failure of the exercises to achieve their object is almost invariably due to incorrect performance, and it is surprising what difficulty certain exercises present to certain patients. As a rule it is obvious when an exercise is being performed incorrectly. On other occasions it may be difficult to appreciate error unless one is alive to certain trick movements which are readily picked up and which often mimic closely the correct method. One exercise commonly ill-performed consists of a slow drawing backward of the neck starting with the chin on the sternum and ending with the neck vertical. The spine is moved segment by segment with the head kept flexed throughout at the atlanto-occipital joint. The object is to strengthen the semispinalis cervicis, to relax the semispinalis capitis and thereby improve the condition of "poking chin" and the symptoms that arise from it. Its correct performance depends on maintenance of flexion at the atlanto-occipital joint; failure occurs when flexion takes place at a lower cervical level.

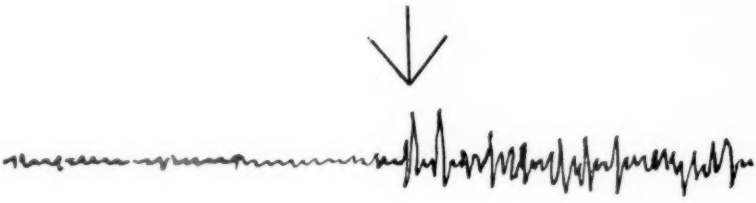

FIG. 7.—Electromyographic tracing with needle in semispinalis cervicis during performance of exercise for "poking chin".

An electromyographic tracing with the needle in the substance of semispinalis cervicis is shown (Fig. 7). In the first part of the tracing the exercise is incorrectly performed with flexion of the neck in the mid-cervical region. In the second part performance is correct, flexion being maintained at the atlanto-occipital joint. The tracing illustrates very well the great difference in motor unit activity when exercises are correctly and incorrectly performed. They also suggest that electromyography may provide a useful means of determining whether a newly devised exercise achieves what it sets out to do.

SUMMARY

(1) A wide definition of normal posture is necessary owing to the variations in physique in members of the community.

(2) Useful clinical information can be obtained from three tests: the plumb line, the pelvic carriage and the pelvic angle.

(3) The common varieties of faulty posture are: (1) Lumbar lordosis; (2) shop-girl's hip; (3) flat back; (4) sway back; (5) dorsal kyphosis; (6) poking chin.

(4) Features constantly found in association with faulty posture are: (1) Inability to relax muscles; (2) loss of agility; and (3) loss of mobility of the spine.

(5) The clinical sequels and accompaniments of faulty posture may be considered under three groups: primary (fatigue muscle pain), secondary (acroparæsthesia, back strain and chronic recurrent cervical fibrositis), and late secondary (osteo-arthritis of the hip and lumbar spine).

(6) Five factors have to be considered in treatment. Improvement of agility, improvement of mobility, re-education of muscular relaxation, strengthening of weak muscles, re-education of the postural reflex. These five factors vary from patient to patient.

(7) Unless treatment is carefully worked out and accurately carried out improvement is not obtained.

DISCUSSION ON THE MANAGEMENT OF RHEUMATIC FEVER AND ITS EARLY COMPLICATIONS

Cardiac Complications

By PAUL WOOD, O.B.E., M.D., F.R.C.P.

IN any patient with active rheumatic fever or suspected rheumatic fever it is vitally important to detect the presence or absence of clinical carditis, for proper immediate and future management depends upon the accuracy of such a diagnosis.

Approximately 5% of the population are known to have acute or subacute rheumatism before they are 20 years old (Parkinson, 1945). Of those recognized at the time, about 5% die within one year, 10% within five years, and 20% within ten years (Coombs, 1924). It is estimated that there are some 200,000 adults between the ages of 18 and 41 with organic rheumatic heart disease in Great Britain at the present time; from the figures quoted above it follows that there would have been about 300,000 had there been no earlier deaths. Not more than 200,000 of these would be expected to give a rheumatic history, the incidence of such a history in all cases of mitral stenosis being about 66%. If the young adult population is put at 10,000,000, then there should be about 500,000 healthy persons who also give a history of rheumatic fever in childhood (Parkinson and Hartley, 1946). It follows that around 70% of cases escape without detectable cardiac damage, or recover from it completely. As the latter event is rare, the statement that carditis may be assumed for all practical purposes in active rheumatic fever cannot be accepted. If 10–20% recover completely from clinical carditis, then 50–60% escape entirely. This calculation agrees fairly closely with clinical observations during the acute stage of the disease. The incidence of carditis at Taplow is higher (72%), but this is almost certainly due to selection, cases recovering quickly having far less chance of being admitted.

The chief signs of active carditis may be listed as follows: (1) Significant mitral systolic murmur. (2) The Carey Coombs murmur. (3) A new or transient aortic diastolic murmur. (4) Cardiac enlargement. (5) Pericardial pain, friction or effusion; or electrocardiographic proof of pericarditis. (6) Elevation of the jugular venous pressure and other evidence of heart failure. (7) Prolongation of the P-R interval or of $Q\text{-}T_c$.

(1) *Mitral systolic murmur.*—A significant mitral systolic murmur is usually early in onset, long, loud and blowing. Follow-up studies reveal that 45% of children with loud murmurs, and only 9% of those with soft murmurs, develop permanent valve disease (Boone and Levine, 1938). Without the help of phonocardiography it is impossible to tell precisely when a murmur begins, and we have no information on this point concerning the early or relatively early mitral systolic murmur. But the late systolic murmur is easily recognized by auscultation and we have heard it in several patients with undoubted active carditis. Moreover, in cases of permanent organic mitral incompetence with a mitral systolic

murmur and thrill, left ventricular enlargement, and systolic expansile pulsation of the left auricle (Figs. 1 and 2) the murmur and thrill may be late (Fig. 3). Expansile pulsation of the left auricle is seen in a small minority of cases of active carditis with loud mitral systolic murmurs: follow-up studies on this group may prove interesting. Advanced organic mitral incompetence presents in two main forms: (1) with left ventricular enlargement (Fig. 3) when it is apt to be confused with aortic stenosis; (2) with aneurysmal dilatation of the left auricle (Fig. 4). Type I tends to develop irreversible heart failure in the fifties; Type II

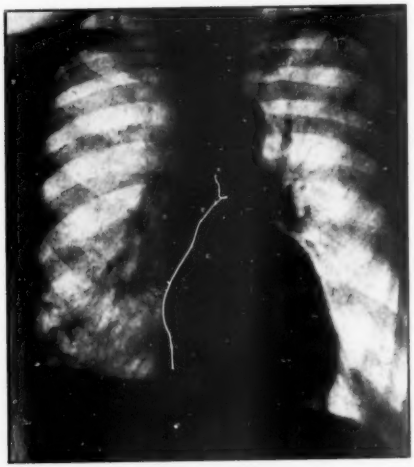

FIG. 1.—Case of permanent organic mitral incompetence showing dilatation of the left auricle.

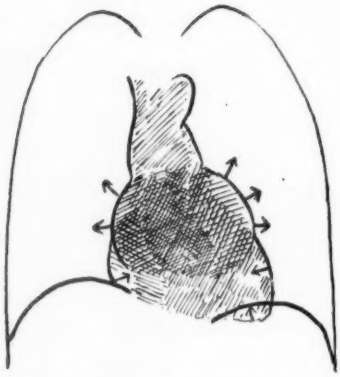

FIG. 2.—Diagram illustrating expansile pulsation of the left auricle during systole.

FIG. 3.—Case of permanent organic mitral incompetence with considerable left ventricular enlargement. In this instance the systolic murmur and thrill were late, and immediately preceded the second heart sound.

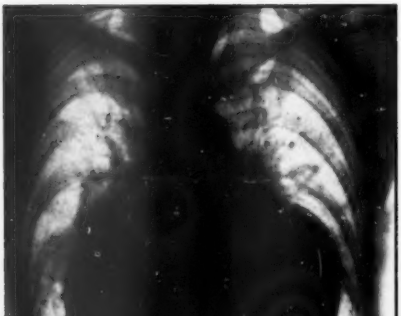

FIG. 4.—Case of organic mitral incompetence with aneurysmal dilatation of the left auricle.

behaves more like mitral stenosis. Early or mild cases are, of course, less characteristic and may show little but the murmur and paradoxical pulsation of the left auricle. Admittedly, organic mitral incompetence is uncommon, but it is hardly rare. I have collected some 20 good examples since 1937, omitting the war years.

(2) *Carey Coombs murmur.*—The notation is used to describe the soft, low-pitched, relatively short mitral diastolic murmur associated with active rheumatic carditis. Though it may be transient or recurrent, it usually persists or may be brought out by special circumstances when all other evidence of activity has subsided. It is heard best with the bell stethoscope during the inspiratory phase of quiet respiration when the patient lies on the left side. When mitral stenosis develops it becomes louder, rougher, and longer, and may be accentuated in presystole. We agree with Carey Coombs that this murmur is probably due to turbulence set up by thickening of the mitral leaflets. It cannot be due to left ventricular dilatation because it is common when the heart is not enlarged.

In a consecutive series of 105 new cases of rheumatic fever at Taplow, there were 75 with evidence of carditis. Of these, 58 developed a Carey Coombs murmur, permanent in 45 and transient in 13. Mitral valvulitis associated with an isolated systolic murmur occurred in only three cases, and these were admitted late in their course.

(3) *Aortic diastolic murmur.*—The first definite evidence of carditis may be a soft, high-pitched, short aortic diastolic murmur. It may be heard only with a Bowles type of stethoscope, being often inaudible with a bell type. A very short gap may be detected between its onset and the second heart sound, as described by Wells at a meeting of the Cardiac Society last year, but it precedes the third heart sound and does not give rise to the same cadence as the mitral triple rhythm. It is usually maximum in the third left space close to the sternal border, but may be louder lower down.

In our series of 75 fresh cases of rheumatic carditis at Taplow, 34 developed an aortic diastolic murmur, permanent in 30 and transient in 4. Combined mitral and aortic lesions occurred in 26 cases.

(4) *Cardiac enlargement.*—We have been disappointed in radiology as a means of detecting the presence of carditis. Enlargement of the heart shadow is unusual unless there is heart failure, pericardial effusion, or old valve lesions. Slight reduction of heart size may follow the subsidence of any fever (Weens and Heyman, 1946); on the other hand, other things being equal, the diastolic heart size is apt to be larger when the rate slows. With the short exposure times in common use nowadays, serial films may show hearts in systole or diastole, a simple trap for the unwary.

As previously stated, conspicuous enlargement of the heart without old valve lesions is nearly always due to failure, and occurs rapidly. The four examples shown died, and necropsy proved that there was no pericardial effusion. In patients who recover from failure enlargement is reversible. In the case illustrated pericardial effusion was excluded as far as possible.

(5) *Pericarditis.*—The occurrence of pericardial pain, friction or effusion provides good evidence of carditis, rheumatic pericarditis never occurring alone. We have experienced some difficulty in diagnosing fibrinous pericarditis without friction and in distinguishing pericardial effusion from a dilated heart in failure. The electrocardiogram has proved unexpectedly disappointing (Fig. 5), the pattern denoting widespread superficial myocardial injury being found in only 25% of proved cases. This is in sharp contrast to tuberculous pericarditis in which the pericardial T2 pattern is seen in practically all. It is suggested that the frequent absence of the current of injury may be due to the lack of a boundary zone between the superficial and deeper layers of the myocardium, owing to coincident carditis. If this hypothesis is correct, one would expect a better prognosis in those showing the current of injury. In fact, the majority of those that exhibited such a graph recovered, whereas the majority of those who did not, died; but the numbers are too few to be statistically significant.

Pericardial effusion may be proved by paracentesis, but a dry tap does not absolutely exclude it owing to the possibility of technical fault or difficulty. Three other methods of distinguishing it from a dilated heart are being investigated. (1) Skiagrams in the prone or supine position may show widening of the vascular pedicle, disappearance of the first inch of the descending aorta, and divergent vascular shadows near the thoracic outlet. So far we have been unable to distinguish pericardial effusion by this method. (2) The Q-T interval is lengthened in rheumatic carditis and tends to be shortened with pericardial effusion. Thus in 12 cases of rheumatic pericardial effusion $Q\text{-}T_c$ averaged 0·36 second, and ranged between 0·32 and 0·40 second. Very few, if any, cases of heart failure from active carditis have $Q\text{-}T_c$ intervals within this range. This is proving a useful method of distinguishing the two conditions provided digitalis has not been given (digitalis shortens the Q-T interval). (3) If the catheter is coiled in the right auricle, its tip can be made to lie against the right

auricular wall (Fig. 6). In pericardial effusion the right border formed by the parietal pericardium may lie well beyond the tip of the catheter (Fig. 7). Angiocardiography offers an alternative means of providing similar information, but is hardly justified in these sick children. Cardiac catheterization is far less unpleasant and is well tolerated.

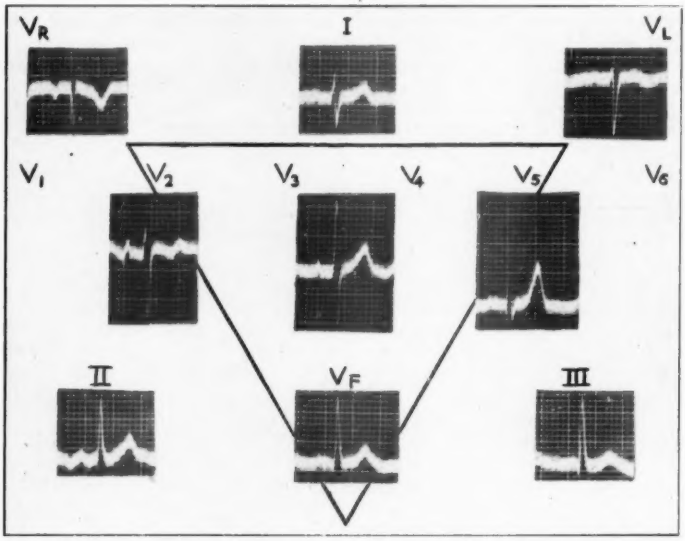

FIG. 5.—Normal electrocardiogram in a case of severe pericarditis proved at necropsy.

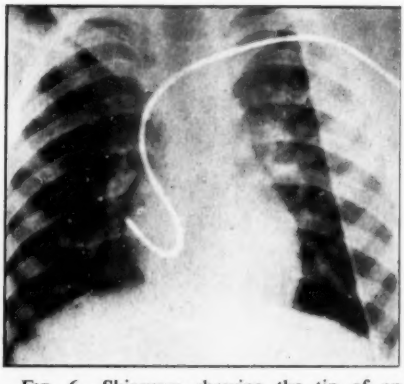

FIG. 6.—Skiagram showing the tip of an intracardiac catheter lying against the wall of the right auricle.

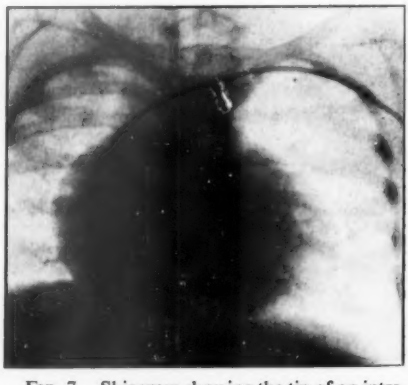

FIG. 7.—Skiagram showing the tip of an intracardiac catheter lying against the right auricular wall in a case of pericardial effusion.

(6) *Heart failure.*—The development of congestive failure is always grave, and the majority die within a few weeks or months. We have several observations to make about failure in active carditis.

(*a*) None of our patients died abruptly. In the literature the incidence of sudden death is also remarkably low—0·04% of cases or less than 1% of all deaths (Griffith and Huntington, 1946). Sitting up suddenly, being transported to the X-ray department for sitting films, cardiac catheterization, digitalis intoxication or reactions to other drugs have never caused ventricular fibrillation or cardiac standstill. In this respect there is a very great contrast

between the behaviour of rheumatic and diphtheritic carditis. Fortunately, the management of rheumatic cases need be influenced by no such ill-founded fears.

(*b*) The erythrocyte sedimentation rate falls in only about a third of the cases. We have not yet attempted to correlate this with changes in hepatic function, but on the whole the greatest drops have occurred in the more chronic instances.

(*c*) A low sodium diet has proved singularly disappointing; indeed heart failure from rheumatic carditis seems almost unique in its lack of response.

(*d*) On the other hand, digitalis may give excellent results. Slowing of the heart-rate, diuresis, loss of weight, increase of vital capacity, and cessation of vomiting accompany the fall in venous pressure and shrinkage of the liver. Cases that do not respond usually die. It is remarkable how well these children tolerate the drug and our early fears of the dangers of overdosage soon evaporated. The effective dose for an average child of about 10 is half rather than a quarter or third of the adult dose. Another interesting point about digitalis in active rheumatic carditis is that it may cause no depression of the ST segment of the electrocardiogram. One cannot help being reminded of the absence of ST deviation in so many of the cases of pericarditis, and wondering whether both peculiarities depend upon a common factor.

(7) *Electrocardiographic evidence.*—Prolongation of the P-R interval has occurred in barely 10% of our cases, but this may be because the majority are not seen early enough.

Prolongation of Q-T_c has proved a much more valuable index of activity. Details have been reported by Abrahams (1949).

Elevation of the ST segment and reversal of the T wave, due to pericarditis, have already been discussed.

The management of cases known to have carditis still follows traditional paths; they are usually kept in bed until all evidence of activity has subsided or until hope of its ever doing so is abandoned. There is no evidence that the natural course of the disease can be influenced in any other way, and precious little that it is greatly influenced by rest. However, it is up to those who believe that physical effort does no harm in the active phase of the disease to prove their point before we can be expected to give up so obvious a remedy.

The General Management of Rheumatic Fever

By E. G. L. BYWATERS, M.R.C.P.

Special Unit for Study and Care of Juvenile Rheumatism, Canadian Red Cross Memorial Hospital, Taplow, Berks

APART from the chemoprophylaxis of rheumatic fever and the use of cortisone and pituitary corticotrophic hormone, there is really very little on this subject that has not been said by many others in the last fifty years. There is, however, a fair amount of controversy over some of these traditional lines of treatment. I think this is largely because we have tended to rely on clinical impressions and inherited beliefs rather than on efforts to secure factual evidence. The great difficulty is, as always in clinical work, that we cannot run the risk of harming the patient by omitting measures we believe to be of value, even though the evidence for that usefulness is poor. We hope to secure data on the effects of treatment in the Special Unit at Taplow but it is much too early yet to give more than general impressions from this experience and although I shall cite particular instances and tentative impressions, we are not yet in a position to produce standard errors and coefficients of correlation.

The relative costs of caring for rheumatic children in their own homes, in foster homes, in convalescent homes and in hospitals are shown in Table I.

TABLE I.—RELATIVE COSTS OF CARE

Home care	:	30–35 dollars/month
Foster-home care	:	45–50 dollars/month
Convalescent home	:	120 dollars/month
Hospital	:	400 dollars/month

These are American figures but there is no reason to think that they differ very greatly (even after allowing for devaluation) from ours. Despite the great difference in cost I am convinced that it is better to care for these children in hospital. Rheumatism is a disease of the under-privileged and there is something in their home environment which is conducive to the disease and to its recurrence. In the occasional case occurring in a well-to-do home, home nursing may be the more desirable.

As existing methods of treatment involve a long stay, a hospital should have a school attached. It means a great deal to a child's psychological development to find when he rejoins his school, as most do after a period of six months or a year, that he has not lost his place and left his friends. It is better for one hospital to take care of the child from the start, as we are prepared to do at Taplow, and see him through: the present practice of admitting to a large general hospital and then after six or eight weeks discharging to a convalescent home is largely an economic makeshift, involving rupture of that personal contact between doctor, patient and family which is the most important factor in after-care.

Differential Diagnosis

The first thing in the management of acute rheumatism is to make sure that the case *is* one of acute rheumatism. The differential diagnosis in some cases is most important.

Table II.—Differential Diagnosis of Rheumatic Fever

In children:	*In adults*:
Appendicitis (19/271, Hansen)	*Subacute bacterial endocarditis*
Growing pains	*Gout*
Poliomyelitis	*Gonococcal arthralgia*
Osteomyelitis	Rheumatoid arthritis
Leukæmia	Lupus erythematosus
Still's disease	
Scurvy	
Congenital heart disease	
Rare blood diseases (Letterer-Siwe, myelosclerosis, sicklæmia)	

Thus in a case presenting as early osteomyelitis of the knee or hip it is far better to treat immediately with large doses of penicillin even if the case ultimately turns out to be rheumatic fever than run the risk of getting bone destruction and its crippling sequelæ. The distinction may be at times extremely difficult in the very early case. Appendicitis is perhaps the only other common difficulty. While it is no disgrace to open up an occasional rheumatic abdomen (because occasionally a true appendicitis occurs and needs such treatment), it seems probable that the majority of right lower quadrant scars in rheumatic fever patients could be avoided if this possibility were present more often in the mind of the surgeon (Hansen, 1943).

Still's disease with fever, joint-pain and swelling, and rash is also occasionally difficult to distinguish in its early stage: the action of salicylates on the fever is not, as used to be so widely taught, diagnostic of rheumatic fever.

Fourthly, clubbing and petechiæ are not always indices of subacute bacterial endocarditis when they occur in rheumatic patients. We have seen clubbing in rheumatic carditis with failure, in the absence of infection and lung disease, and it has receded completely as the child recovers. Such cases should not be allowed to vitiate the statistics of cured subacute bacterial endocarditis.

Rest in Bed

Management of rheumatic fever is based on the fact that it is a self-limited disease and the only sequelæ of any importance are the cardiac lesions. If these could be aborted the disease would be of no more importance than mumps. It has long been thought that the heart is less damaged if its work be cut down to the basal requirements of 40–50 cals/sq.m./hr. An extremely interesting analogy is poliomyelitis where Ritchie Russell (1949) has shown that severe paralyses occur in those who have indulged in considerable physical activity during the prodromal period. This cardiac rest is best achieved by keeping the patient lying flat in bed. Although it is known that the work of the heart is slightly more in the flat position than in a sitting position, the curtailment of activity is so much greater that the *total* cardiac work (as distinct from the *basal* cardiac work) is actually less, because less movement is possible. The evidence for this hypothesis that rest minimizes residual cardiac damage is scanty (Sibson, 1877) and it rests largely on clinical impressions. Perhaps the best evidence available is that of Taussig and Goldenberg (1941). They observed that of a group of children showing progressive enlargement of the heart and a 50% mortality, only half had been treated with bed rest and then only for a short time, whereas in other groups which showed no

progressive enlargement and a 6% mortality only, 98% had adequate periods of prolonged bed rest. As I have said before, few physicians, unless they hold strong beliefs to the contrary, would risk the ultimate wellbeing of their patients by omitting such prolonged rest. Yet in Chicago I have recently been shown a camp where children are encouraged to lead an active supervised life—boating, swimming, &c.—even though they may have an E.S.R. in the neighbourhood of 40 mm./hr.: the only criterion is that the E.S.R. should be beginning to show a definite fall. It is claimed that no harm results from this. Unfortunately the assessment of such measures involves a long survey and follow-up of a large number of rested and non-rested cases and that requirement has not yet been fulfilled.

Criteria of Rheumatic Activity

The critical question, accepting rest as the most important measure in the treatment of rheumatism, is "for how long?" and, on the above hypothesis, it should be not for any arbitrary period of six months but until carditis has completely subsided. What criteria should we use for this? Fig. 1 shows the criteria that we are actually using at Taplow. It

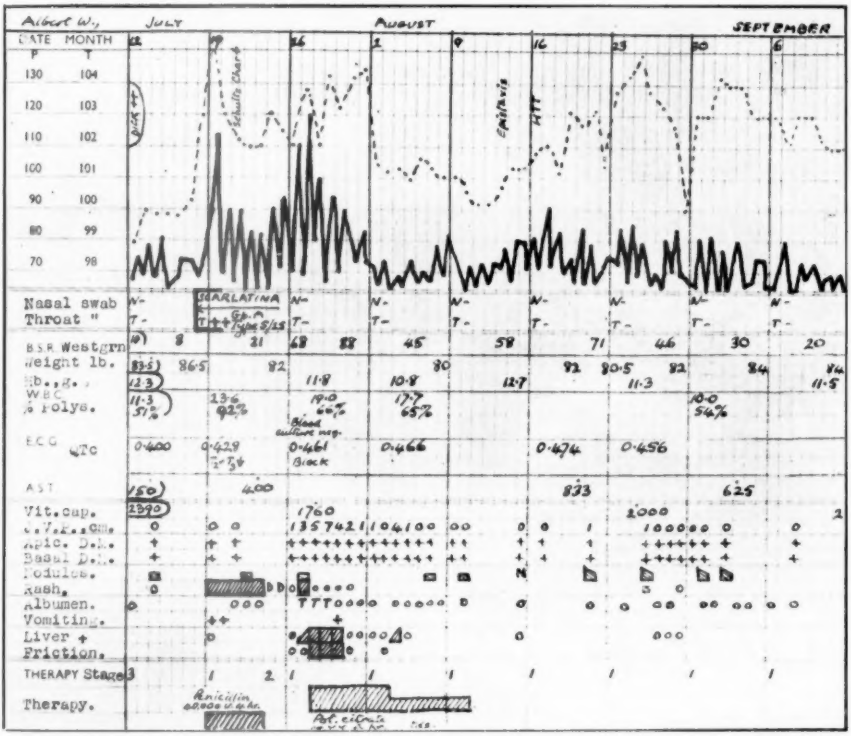

Fig. 1.—Routine ward chart (Canadian Red Cross Memorial Hospital, Taplow), showing rheumatic attack following scarlatina.

shows an attack of scarlet fever occurring in a convalescent rheumatism patient. Of the clinical observations, pulse and temperature are important but some children will show bradycardia during the active phase and some are afebrile. Hæmoglobin rise indicates recovery but it may be delayed. The white blood count is of only limited value. The anti-streptolysin O titre merely indicates a previous Group A hæmolytic streptococcus infection and is of no value in this respect at all. The sedimentation rate is one of the most useful of criteria and is perhaps more widely used than any other. We depend largely on the weekly sedimentation rate and prefer the Westergren technique. We feel that correction for anæmia is worse than useless: anæmia itself is an indication of activity and adds to the value of the

reading. There is also less packing than in the Wintrobe tube for the hour reading. It should be remembered, however, that there are certain fallacies in this test. Firstly, during failure, sedimentation rate may fall, as Payne and Schlesinger showed in 1932. Secondly, salicylates, admixture of alcohol in the syringe and a low ambient temperature depress the sedimentation rate. Thirdly, a high E.S.R. may occur in adolescent girls without rheumatic activity, shown in Fig. 2. The high level may be maintained for months or it may finally become normal.

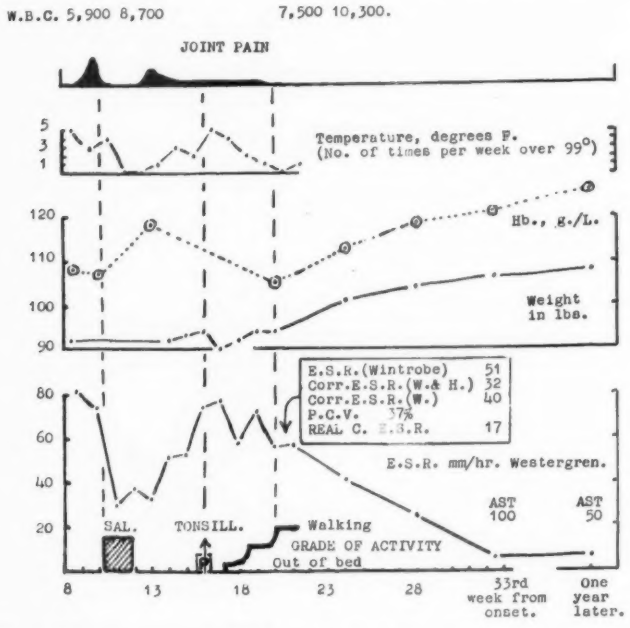

FIG. 2.—Chart showing decrease in E.S.R. with salicylates. No evidence of carditis. Recovery from the time of tonsillectomy. Mobilization with a high E.S.R. without ill-effect judged by the weight gain, hæmoglobin rise and E.S.R. fall. Theoretical correction of E.S.R. for anæmia fallacious. Actual correction showed an E.S.R. within normal limits. M. S., female, aged 13 years. Fever and joint pain one week after tonsillitis.

In this case we endeavoured to correct the E.S.R. for anæmia using both Whitby and Hynes', and Wintrobe's correction charts, but there was no marked alteration. When, however, we corrected to a standard hæmatocrit by removal of plasma, we got an E.S.R. within normal range and subsequently it returned completely to normal. The chart illustrates well that patients, particularly adolescent girls, should not be kept at rest solely because of a high E.S.R. in the absence of other signs of activity since mobilization in this case actually produced the fall towards normal of the apparently abnormal reactions.

Another criterion which has been proposed by Taran is the corrected QT interval,— $\sqrt{\frac{QT}{R\text{-}R}}$ and Abrahams (1949) has undertaken a preliminary investigation of our cases from this point of view.

In many cases of carditis we have found that the QT_c falls from its initial abnormal levels to normal during recovery parallel with the E.S.R. When children with a QT_c above the normal upper limit of 0·43 sec. but with a normal E.S.R. are got up, the E.S.R. may rise and although we do not know whether this indicates increased rheumatic activity and cardiac damage or merely a non-specific serological change, we feel it is wise to act as though the former were happening and we therefore put the child back to bed. Fig. 3, however, shows that some children may be got up with markedly abnormal QT_c without ill-effects and we think that such exceptions underline our general attitude at Taplow that no one test is adequate as a criterion.

May Wilson (1940) places high value on the vital capacity. Fig. 4 shows that this does

FIG. 4.—Chart showing congestive heart failure with rheumatic activity. As soon as activity subsided (judged by E.S.R. fall) the patient came out of heart failure (judged by J. V. P.) and the weight and vital capacity rose. Mobilization at the 70th week to Grade 4 and then successfully to Grades 5, 6 and 7 without incident.

FIG. 3.—Mobilization from Grades 4 to 7 (out of bed, walking, etc., to full activity) in the presence of increased QT_c and normal E.S.R. without effect on recovery judged by clinical signs, weight increase and E.S.R. Two temporary setbacks due to tonsillectomy and glandular fever.

coincide very well with other criteria but it is of value chiefly in patients who are recovering from congestive failure. Gain of weight due to putting on flesh, and not due to acute episodes of congestive failure with water retention, is perhaps the least fallible of all these criteria but the change is a comparatively slow one. A well-sustained rise in weight, however, is a very good indication in children that the rheumatic process is over.

In summary, therefore, we feel that bed rest should be maintained until most or all of the criteria we are using (amongst which the most useful are sedimentation rate and electrocardiographic change) are normal and then the patient should be gradually mobilized and a close watch kept on these signs of activity. This applies more to children than to adults in whom cardiac damage is less frequent and who seem to bear a much earlier mobilization with impunity.

Ward Routine

General ward routine is designed to guard against cross infection. New cases are isolated until they are proven to be free from hæmolytic streptococcal infection: a weekly nose and throat swab is taken from all patients and all staff, carriers being isolated, organisms grouped and typed, and persistent carriers sterilized with penicillin. Oiling of the floor and bedclothes has been advocated to cut down cross infection but we have had no personal experience of this. Massell, Dow and Jones have recently claimed that rheumatic fever recurrences following hæmolytic streptococcal sore throat have been cut down from about 50% to nil in a small series of 15 cases treated with penicillin immediately after discovery of the sore throat. This seems theoretically possible since cases thus treated show a very much smaller antibody rise but it depends upon the length of time the infection takes to produce symptoms. We have found that in one case prompt treatment with very large dosage within a few hours of the first tickling of the throat was not sufficient to prevent a severe rheumatic recurrence. It may turn out, however, that the majority of cases can be thus treated in time and if so this is very important indeed.

Salicylates

We come now to "specific" therapy and the salicylate problem. Salicylates although used now for nearly three-quarters of a century are still a controversial subject, and a great deal of argument still occurs as to their action. Despite Coburn's claim that blood levels above 35 mg.% "cure" rheumatic fever, we believe rather that it does little more than relieve the symptoms and mask the evidence of activity. It has been shown at this serum level to depress the E.S.R. in non-rheumatic subjects as well as in rheumatic subjects (Harris, 1947). It decreases fever (in other conditions as well as in rheumatism) and it relieves the pain of joint lesions, but other signs of joint involvement, such as the skin temperature (according

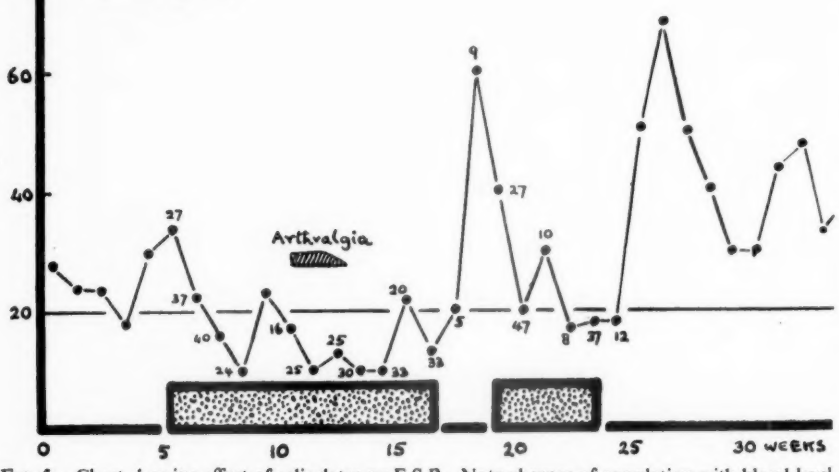

FIG. 5.—Chart showing effect of salicylates on E.S.R. Note absence of correlation with blood level. (Read blood levels in mg.% across chart.)

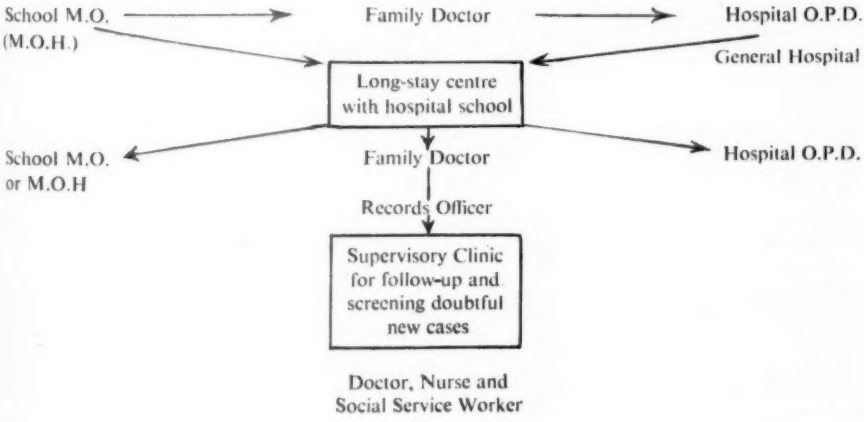
to Murphy, 1945) and the effusions frequently persist. On both these counts, that is pain and fever relief, salicylates are invaluable in treatment and the lessening of the fever must reduce the work of the heart. If, however, a course of salicylates is interrupted the E.S.R. will frequently rise to its preceding high level (Fig. 5) and indeed we have seen chorea, pericarditis and nodules occur during salicylate treatment as also have others. Furthermore in the severe and active cases with heart failure, salicylate will not arrest the fatal termination. Its toxicity is in some cases a drawback although seldom very severe. Apart from the rare sensitivity reaction with puffy eyes, &c., it produces a respiratory alkalosis due to direct stimulation of the respiratory centre with a secondary depression of CO_2 combining power. It is a mistake to treat this lowered alkali reserve with alkali as it may raise the blood pH still further and precipitate a bad alkalosis. It may produce an alarming but luckily transient psychotic state. Bleeding due to prothrombin depression is seldom seen and is said to be relieved by vitamin K (1 mg. of the synthetic product is equivalent to 1 gramme of salicylate). We have debated whether salicylate bleeding in the basal areas of the brain might be responsible for the occasional hyperpyrexia against which continued salicylates seem ineffective and which should be treated by tepid baths. Recently Meyer and Ragan have reported that sodium gentisate, a breakdown product of salicylates, is just as effective and less toxic. There should be a future for such a drug.



The most spectacular advance in this field is the use of cortisone and ACTH by Hench, Kendall and their colleagues from the Mayo Clinic. ACTH from pig pituitary and cortisone from bile, primarily used in rheumatoid arthritis, have been found by Hench equally successful with rheumatic fever. The QT_c interval, calculated from his data, together with other criteria of activity, shows a decrease within a period of ten days. I have seen other cases treated with ACTH at the House of the Good Samaritan in Boston by Thorn, Massell and Forsham with remarkable improvement but as one of their colleagues remarked: "It seems nearly as good as aspirin, but a bit more expensive." The assessment of its value is much more difficult than in rheumatoid arthritis since rheumatic attacks may be spontaneously terminated within a comparatively short time and it will need a more detailed and critical selection of cases to prove this point if reliance is to be placed on individual case records rather than on statistically controlled investigation which, at the moment, supplies of the substance do not allow. Ultimately it may prove that such hormone treatment is more useful in rheumatic fever than in rheumatoid arthritis since it does not need to be continued for a period of many years.

As in rheumatoid arthritis, there is no evidence in rheumatic fever of a primary hypothalamic, pituitary or adrenal deficiency since the response to adrenaline is normal and we are left with the hypothesis that there is an acquired connective tissue disorder on which the hormones act.

After-care

The management of rheumatic fever involves the care of the child after leaving hospital. The London County Council have been pioneers in this respect and we have adopted their system of supervisory or advisory clinics for looking after the health of the child and of its family following discharge from hospital.

TABLE III

The groundwork for this is laid by getting to know the parents while the child is still in the hospital. It is important also to see that harmonious contact is maintained with the responsible School Medical Officer, the family doctor and the referring hospital. We send copies of the in-patient summary with recommendations regarding physical activity, school, &c., to each of these authorities. This supervision should continue certainly during the next two or three years and preferably through adolescence, since May Wilson has shown clearly that the risk of recurrences is greatest within a short period of the last attack and in the age-group up to 15 (Wilson and Lubschez, 1944). General instruction on avoidance of exposure to infection, damp, chills, and limitation of physical activity if necessary, on school arrangements, housing problems, re-employment for the older children, are all given at this level. It is in the prevention of further recurrences that the co-ordination of the social and the health services is so necessary: and it is in this after-period that the problem of chemo-prophylaxis becomes so important.

Oral Penicillin in the Prophylaxis of Streptococcal Infection and Rheumatic Relapse

By J. A. PITT EVANS, M.B., B.S.

INTRODUCTION

THIS is a preliminary report of an investigation into the value of penicillin in the prevention of streptococcal infections among children in a Home for convalescent rheumatic fever patients. The work was carried out by a team of laboratory and clinical workers under the direction of Professor Robert Cruickshank.

American, and more recently Australian, workers have found that small doses of sulphonamide (1 to 2 grammes daily) have a prophylactic effect on the occurrence of rheumatic fever relapses by preventing the occurrence of streptococcal infection which is a common precursor of such relapses. However, sulphonamide given over a long period, even in small doses, may produce toxic effects including granulopenia so that some laboratory control, e.g. weekly blood counts, is commonly recommended with prolonged administration. This prophylactic method is therefore unsuitable for most Convalescent Homes where laboratory facilities are poor, and more so for domiciliary practice. There is the added risk of producing sulphonamide-resistant strains of hæmolytic streptococci.

Penicillin is practically devoid of toxicity and is particularly active against the hæmolytic streptococcus which does not readily become drug resistant. Ordinarily penicillin is given by injection but such a method would be quite unsuitable for prolonged use. There is evidence that penicillin given by mouth on an empty stomach is absorbed (if rather irregularly) and that about five times the amount of an intramuscular dose is required to give equivalent blood levels. We therefore decided to try the effect of one daily dose of 100,000 units of penicillin given in 5% glucose (which encourages absorption) before breakfast. Such a dose should with most cases give a maximum blood level of 0·4 to 0·5 unit of penicillin and maintain a bactericidal level against the hæmolytic streptococci for two to three hours.

Children of 5–13 years of age are admitted to the Lancing Convalescent Home for a maximum stay of six months so that they can be followed only for a short period after the attack. However, Wilson and Lubschez have shown that the highest incidence of rheumatic relapses occurs in the first year after an attack and in the age-groups 5–13 years. It might therefore be expected that a number of relapses would occur among the children during their stay in the Home, and this was strongly supported by an analysis of the earlier records. Our main objective, however, was to study the effect of prophylactic penicillin on clinical and latent streptococcal infections among these children.

Details of Scheme

The scheme was started on November 9, 1946, and continued until September 30, 1948, and was carried out at the Children's Heart Home, Lancing, which caters for rheumatic fever convalescents, recruited from a wide area. On admission each child was allocated by random sampling to penicillin or control group. Subdivisions into the sexes and two age-groups 5–8 and 8–13 were made. The treated and control groups mixed freely throughout the scheme.

The penicillin group received 100,000 units of calcium penicillin in ½ oz. of 5% glucose three-quarters of an hour before breakfast. The control group received nothing. No toxic reactions or ill effects from the penicillin were reported during the two years' study.

The clinical side of the investigation was under the charge of Dr. Whiting, the local practitioner, with periodic visits from Dr. MacCarthy whose opinion as to what constituted clinical evidence of fresh rheumatic activity has been taken as final. These included joint swellings, or joint pains with limitation of movement, erythema marginatum, pericarditis, carditis, and subcutaneous nodules; most of these manifestations to be accompanied by rise of temperature and tachycardia.

The laboratory side of the investigation was my responsibility and was as follows:

(*a*) Weekly nose and throat swabs were collected from the children and plated out on the same day at the beginning of the scheme and after overnight refrigeration during the second half of the investigation; all hæmolytic streptococci were grouped and typed.

(*b*) Approximately once a month all children had a venepuncture and the sedimentation rate and anti-streptolysin O-titre estimated. The diagnosis of streptococcal infection required the isolation of Lancefield group A hæmolytic streptococci and as a rule a two-tube or more rise in the anti-streptolysin O-titre.

During the twenty-three months of the investigation, 155 children received penicillin and 145 acted as the control group.

The results have been analysed to compare (1) the incidence of hæmolytic streptococcal carriers in the two groups; (2) the incidence of clinical streptococcal infection; and (3) the occurrence of rheumatic relapses or evidence of fresh rheumatic activity.

Table I shows the incidence and duration of streptococcal carriers in the two groups with ratios of approximately 4 : 1 in favour of the penicillin group. It should be noted that

Table I.—All Children in the Survey: Incidence of Streptococcal Carriers

	Penicillin	Control
Total No. of patients	155	145
No. of patient-weeks in home	3,345	3,248
Average length of stay in weeks	21·6	22·4
No. of patient-weeks H.S.* carried in throat	71	242
No. carrying H.S.* in throat for two consecutive weeks	7	33
No. carrying H.S.* in throat for 3 consecutive weeks	4	17

*Group A hæmolytic streptococci.

the two groups are approximately equal as regards the number of cases and the length of time that they were in the Home.

Table II shows the incidence of clinical streptococcal pharyngitis or tonsillitis in the two groups. *In the penicillin series*, the one doubtful case was a girl with chronic tonsillar infection with occasional exacerbations. *In the control group* there were 7 definite cases of tonsillitis due to Lancefield group A streptococci: in 6 of these cases there was a rise in the anti-

TABLE II.—CLINICAL STREPTOCOCCAL PHARYNGITIS

Penicillin group	Control group
1 doubtful case (H.S. + No rise of A.S.O.)	7 definite cases with H.S. (group A) (Rise of A.S.O.* in 6 cases) 2 doubtful cases (H.S. negative. Rise of A.S.O.)

*A.S.O. = anti-streptolysin O-titre.

streptolysin titre, and in 5 the E.S.R. was also increased. The two doubtful cases had typical infections with rise of A.S.O. but hæmolytic streptococci were not isolated from their throats during the acute stage. One of these patients had been given sulphonamides at onset and this may have eliminated the hæmolytic streptococci. There were two other clinical cases without hæmolytic streptococci or rise of A.S.O.

As far as rheumatic relapses are concerned, there were none in the penicillin group and 4 cases in the control group. Graphs were shown to illustrate the main laboratory findings in 3 of these cases.

The evidence therefore indicates that a daily dose of 100,000 units of penicillin given orally on an empty stomach has considerable value as a prophylactic against streptococcal infection and consequently rheumatic relapses among rheumatic children in a Convalescent Home.

[*November* 22, 1949]

Pulmonary Changes in the Reticuloses

By NEVILLE OSWALD, F.R.C.P.

IT is to be expected that the lungs, with their abundance of reticulo-endothelial cells and rich blood supply, will often be affected in such general disorders as the reticuloses. Lymph glands may enlarge; those in the mediastinum may cause pressure on veins resulting in pulmonary œdema and pleural effusions; pressure on bronchi may lead to atelectasis; the broncho-pulmonary glands, which are situated at the bifurcations of bronchi as far out as their third divisions, may give rise to masses within the substance of the lungs; any of these glands may be unable to contain actively proliferating reticuloses, which may penetrate their capsules and invade the adjacent pulmonary parenchyma. The peripheral parts of the lungs may be the site of infiltrations which have a wide range of radiological appearances; they may be diffuse from capillary exudation, finely nodular from proliferation in the lymphoid follicles or even miliary; there may be roundish masses as a result of blood-borne metastases from the more malignant types of reticulosis, such as lymphosarcoma. Vascular changes are common in the acute and subacute reticuloses; masses of abnormal cells are often seen blocking the capillaries and smaller blood vessels leading to thrombosis, and infarction is one of the chief causes of pulmonary consolidation. Capillary hæmorrhages may occur as a result of pulmonary congestion and abnormalities in the circulating blood. Pulmonary cavitation is unusual; it may take the form of a lung abscess complicating pneumonia or infarction, or there may be an associated pulmonary tuberculosis; occasionally lymphadenomatous glands break down, whether or not they have been treated by irradiation. Last, there are non-specific infections, which particularly have to be remembered in acute leukæmia where there is inflammation and ulceration in the upper part of the respiratory tract; bronchopneumonia frequently develops as a terminal event.

These changes are to a large extent characteristic of the reticuloses in general, most of them having been described at some time or other in the individual diseases.

Hodgkin's disease.—Rather more than one-half of all cases show abnormal radiographs of the chest, usually in the form of enlarged mediastinal glands or, less frequently, pleural effusions. Roughly one in ten shows changes in the lungs themselves. This last group can conveniently be divided into four.

(*a*) Involvement of glands: It is evident, either on radiological or pathological evidence, that the lymph glands can most conveniently be divided into the paratracheal, tracheo-

bronchial and broncho-pulmonary groups. The tracheo-bronchial glands in the region of the bifurcation of the trachea are most commonly affected and the lymphadenomatous infiltration often extends upwards and downwards to involve all three groups (Fig. 1).

(*b*) Pressure effects of enlarged glands: This may lead to collapse of lung, œdema and pleural effusion (Fig. 2).

(*c*) Roundish masses in the substance of the lungs which are clearly beyond the bounds of the broncho-pulmonary glands and usually represent blood-borne metastases (Fig. 3).

(*d*) Parenchymal infiltration, which shows great variation in extent and distribution and resembles pulmonary tuberculosis (Fig. 4).

FIG. 1.—Widespread infiltration of glands in Hodgkin's disease.

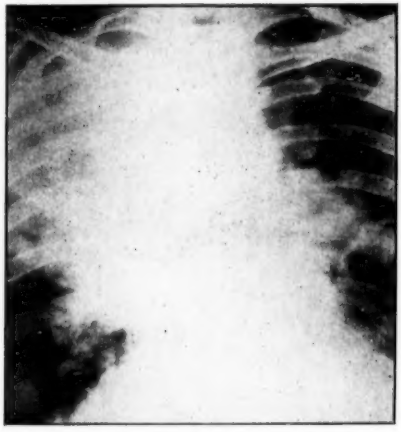

FIG. 2.—Collapse and consolidation of the upper lobe in Hodgkin's disease.

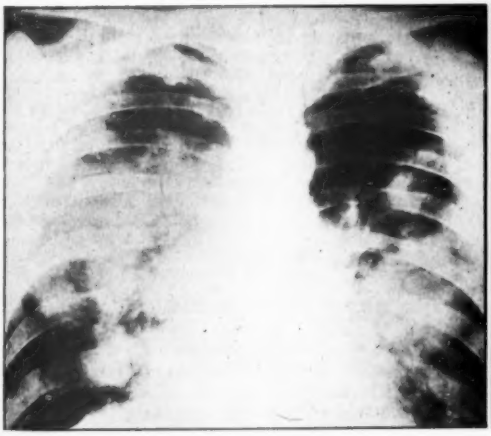

FIG. 3.—Roundish masses in the periphery of the lungs in a case of Hodgkin's disease which underwent sarcomatous degeneration.

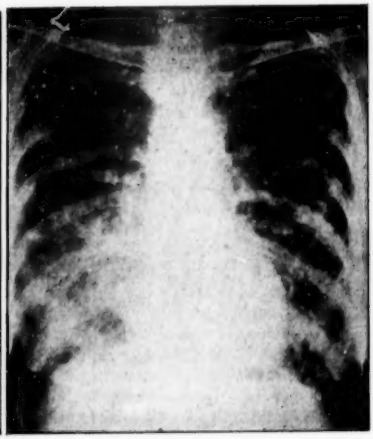

FIG. 4.—Widespread infiltration of the lungs in Hodgkin's disease without radiological evidence of glandular involvement.

Closely related to lymphadenoma is that triad of diseases, *lymphosarcoma*, *lymphatic leukæmia* and *mycosis fungoides*. Abnormal radiographs of the chest occur about one in five, again mainly in the form of enlarged mediastinal glands or pleural effusions. When the lungs themselves are invaded, the radiological appearances are indistinguishable from each other or from Hodgkin's disease, though the rate of progress in the latter tends to be rather slower.

A lady of 57 gave a six-years' history of progressive skin lesions which were proved, on biopsy, to be mycosis fungoides. Three months before death her lesions appeared to be limited to the skin and a radiograph of her chest showed no abnormality. During the last two months of her life she rapidly went downhill and a further film showed rounded masses in both lungs (Fig. 5).

Autopsy revealed similar masses in the liver, thyroid and œsophagus. The sudden terminal dissemination of mycosis fungoides is by no means unusual, even after a great number of years; the lungs are often affected, usually in the form of multiple rounded deposits.

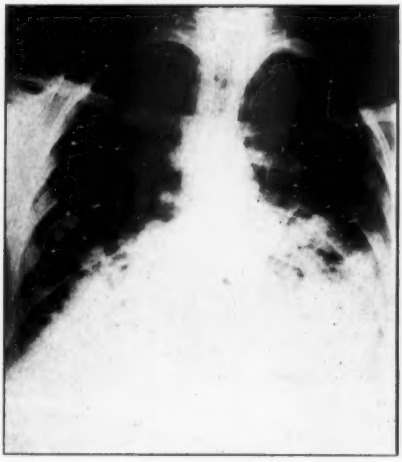

FIG. 5.—Pulmonary involvement in mycosis fungoides.

FIG. 6.—Nodular infiltration in chronic myeloid leukæmia.

The pulmonary changes in *chronic myeloid leukæmia* are usually slight and inconclusive. Occasionally there are somewhat enlarged mediastinal glands and rarely there is a diffuse infiltration of the lungs with fibrosis and infarction.

A man of 57 had suffered for several years from a generalized rash which had been diagnosed as pityriasis lichenoides, a diagnosis which, I am informed, is used in cases of doubt to indicate a condition of uncertain ætiology. For three years he suffered from increasing breathlessness and bronchitis, during which he had two prolonged attacks of bronchopneumonia. Radiographs showed a nodular type of proliferation of lymph follicles similar to that seen in silicosis and sarcoidosis (Fig. 6). His blood count showed 88,000 white cells, almost all of which were of the myeloid series. Autopsy revealed a typical myeloid leukæmia of the marrow, spleen, liver and lymph glands. The lungs showed a generalized fibrosis together with aggregations of myeloid cells in the lymph follicles and peribronchial lymphatics, together with thrombosis in the smaller blood vessels.

In *acute leukæmia* about one-third of all cases, particularly the monocytic variety, have acute inflammatory lesions in the upper respiratory tract. Pulmonary lesions are often dramatic and comprise pneumonia, infarction, œdema and the outpouring of immature cells. Pathological interpretation is often difficult as the white cells in the lungs are the same as those in the blood. Partial and complete thromboses are very common and most of the larger lesions in cases in the literature are considered to have started as infarcts. These occasionally break down and form cavities which often give little in the way of symptoms.

A man aged 48 developed acute monoblastic leukæmia. He had a sudden onset of pneumonia which never appeared to resolve satisfactorily. A month later he developed ulceration of his throat and gums with enlarged glands in the neck which persisted. His general condition steadily deteriorated and he died six months after the onset of symptoms. His white blood-count varied from 4,000 to

100,000 and usually contained about 70% of blast cells and monocytes. A radiograph showed bilateral lesions which resembled tuberculosis, but consisted of consolidation secondary to infarction as proved at autopsy (Fig. 7). The liver, spleen and lymph glands showed a typical monoblastic reaction.

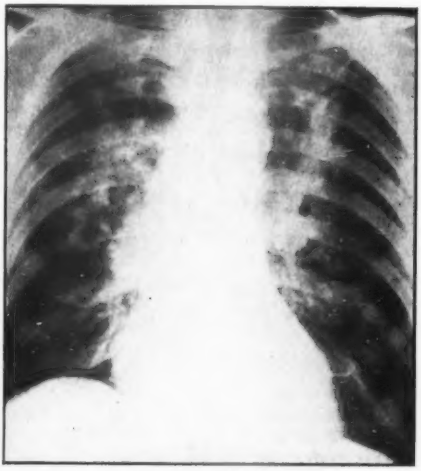

FIG. 7.—Infarction in both lungs in acute monoblastic leukæmia.

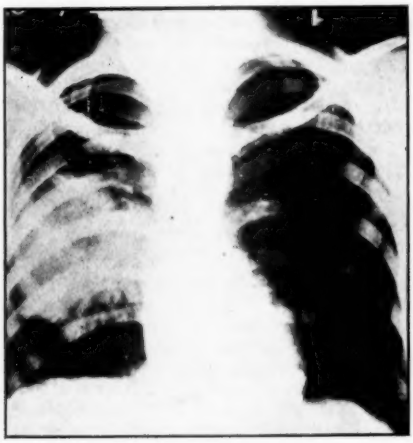

FIG. 8.—Pneumonia with abscess formation in acute myeloblastic leukæmia.

A boy aged 14 was admitted to hospital suffering from acute myeloblastic leukæmia. His illness started with septic lesions of his fingers which failed to heal, lassitude, sore throat with ulceration and enlarged glands in the neck. He died after progressive emaciation at the end of six months. His white blood counts were in the region of 200,000 with an average of 90% of primitive myeloid cells. One month before death he developed an irritating cough and rise in temperature which coincided with an increase in the ulceration of his mouth. His pulmonary symptoms were slight and a film of his chest two months previously had shown no abnormality. Radiographs now showed a roundish lesion with a cavity in the centre in his right midzone (Fig. 8). Autopsy revealed a mass of consolidation in the dorsal segment of his right lower lobe with a subacute abscess cavity in the centre. There was no evidence of tuberculosis or infarction. In view of the oral sepsis and the site and behaviour of the consolidation, an aspiration pneumonia with subsequent breakdown is the obvious explanation. The bone-marrow, liver, spleen and lymph glands showed the characteristic changes of acute myeloblastic leukæmia.

We now come to a group of diseases which are related to *disorders in lipoid metabolism.* In Gaucher's disease, which usually runs a prolonged course, pulmonary involvement is rare. Myers (1937) reported a case of considerable mediastinal glandular enlargement with dense shadows radiating out from the hila almost to the periphery of the lungs; at autopsy the lungs and mediastinal glands were packed with Gaucher's cells. Merklen *et al.* (1933) repeatedly found Gaucher's cells in the sputum of an advanced case.

In Niemann-Pick's disease, which is uniformly fatal before the age of 3, there may be an outpouring of large pale cells into the lungs as part of the general disease process. Canmann (1944) reports a case in which many of the alveoli were packed with such cells. Apart from œdema and congestion there are no characteristic pulmonary changes.

Next there are three conditions which appear to be varieties, or even stages, of the same disease. First there is the Letterer-Siwe disease which is an acute aleukæmic reticulosis of infants, giving rise to fever, anæmia, enlarged liver, spleen and lymph glands, which ends fatally in a few months and has as its characteristic cell a large non-lipoid-containing mononuclear. Secondly there is Hand-Schüller-Christian disease with its classic triad of exophthalmos, diabetes insipidus and erosions of the skull which is less rapidly fatal, usually affects children and is associated with the proliferation of large mononuclear cells containing cholesterol. The third condition has been termed eosinophilic granuloma of bone

(Lichtenstein and Jaffe, 1940); large bony erosions occur which resemble cysts and contain masses of eosinophilic cells. There may be an increase of eosinophils in the other organs which contain reticulo-endothelial cells and in the blood; older children are commonly affected and the disease in a pure form may run a chronic course. Post-mortem examination often shows a mixture of two, or even all three of these diseases. So far as the lungs are concerned, the changes are very similar regardless of which predominates elsewhere, and are quite different from anything seen in any of the other diseases of the reticulo-endothelial system. The lesions are diffuse throughout both lungs. In the early stages there would appear to be a proliferation of reticulo-endothelial cells which soon gives place to a generalized granulomatous infiltration; this in turn may lead to fibrosis and cyst formation, giving a honeycomb appearance. Microscopically, there is a mixture of inflammatory cells, eosinophils and, sometimes, the characteristic large mononuclears which may contain lipoid. Thannhauser (1940), and more recently Parkinson (1949), use the rather unwieldy term "eosinophilic xanthomatous granuloma" to embrace all these changes; this has the advantage of describing such pulmonary changes when evidence elsewhere in the body of one of these diseases is not forthcoming; also, it is usually impossible, on examination of the lungs alone, to tell with which disease one is dealing since the large mononuclear cells are usually scanty, as a result of secondary infection, by the time death occurs.

Finally we come to the *leukæmoid states* in which there is a leucocytosis with immature cells in association with some entirely different disease. Such patients are usually ill and the presence of acute leukæmia has to be proved or excluded. The liver, spleen and lymph glands may be enlarged, but on section show none of the typical histological changes of a leukæmia. Forkner (1938) stresses two points in clinical differentiation, namely that in acute leukæmia there is nearly always a marked decrease in the number of blood platelets, and that almost constantly there are at least 70% and usually 80% of white cells of a uniform and immature type, neither of which features is often seen in leukæmoid states. Amongst the pulmonary conditions which may provoke this response, we are all familiar with pneumonia in infants and young children, in whom such a leucocytosis is quite common. Whooping cough, which normally produces a relative lymphocytosis, may lead to a rise in white cells to 100,000 or even 200,000 per cubic millimetre nearly all of which are lymphocytes; cases recorded with these high figures have nearly always been complicated by bronchopneumonia.

Pulmonary tuberculosis may be associated with a leukæmoid response, which is usually of the myelogenous type. It is an unwelcome sign, the majority of recorded cases having died from miliary tuberculosis within a few months of discovery of the abnormal blood picture.

A carpenter aged 25 was admitted to hospital with one week's history of lassitude, cough and breathlessness, his wife having died from pulmonary tuberculosis some four months previously. On admission, his temperature was 102° and a radiograph of his chest showed infiltration of the left lung with a moderate-sized pleural effusion. His effusion rapidly increased and several pints of turbid amber fluid were aspirated, from which one atypical acid-fast bacillus was isolated. His sputum contained tubercle bacilli. He rapidly went downhill in hospital with high fever and died six weeks later.

Autopsy revealed scattered nodules of caseous bronchopneumonia in both lungs with a superimposed miliary tuberculosis. The mediastinal lymph glands were enlarged and caseous. The liver, spleen and kidneys were riddled with miliary tubercles.

The post-mortem appearances suggest that he died from an overwhelming primary infection, there being a severe primary complex in the chest which gave rise to a miliary dissemination. A chart of his blood picture (Table I) shows weekly blood counts during

his stay in hospital. It will be noted that there were never as many as 70% of cells of a uniform and immature type, and that the last three blood-counts approached normal figures. In addition, there was no change in the spleen or lymph glands at autopsy to suggest a leukæmia.

The whole subject of the leukæmoid reaction is a difficult one, and there would seem sometimes to be no strict dividing line hæmatologically between it and the leukæmias. As an additional complication, leukæmic patients are prone to develop pulmonary tuberculosis.

I would like to thank Drs. Maurice Davidson, E. R. Cullinan, R. Bodley Scott, J. G. Scadding and R. M. B. MacKenna for allowing me to record their cases.

A Ten-Year Follow-up of Peptic Ulcer Cases with Special Reference to Results of Medical Treatment [*Abstract*]

By LAURENCE MARTIN, M.D., F.R.C.P.
Addenbrooke's Hospital, Cambridge

356 proven cases of peptic ulceration which had been admitted as in-patients to Addenbrooke's Hospital during the years 1934–38 inclusive were followed up in 1948–49. Of the total, 142 had died, 195 were traced, and 19 were untraced. Of those traced 96 gastric and 43 duodenal ulcer cases had been treated by medical means alone with or without the simple suture of a perforation. At follow-up 42 (44%) of the 96 gastric and 14 (32·5%) of the 43 duodenal ulcer cases were inactive and had been free from symptoms for the previous five years. After full enquiry into the regimen of treatment which had been followed by each patient during the follow-up interval it was concluded that medical treatment had not influenced the natural course of the peptic ulcers. For a full account of the whole survey *see* Martin, L., and Lewis, N. (1949) *Lancet* (ii), 1115.

The Respiratory Factor in Ankylosing Spondylitis

By F. DUDLEY HART, M.D., F.R.C.P.

Middle-aged man; complaining of breathlessness on exertion. After X-ray examinations and investigations he was diagnosed as a case of emphysema. But on his third attendance at hospital he was correctly diagnosed by an assistant, who had also worked in the Rheumatism Clinic, as a case of ankylosing spondylitis.

History.—In the trenches in the first World War in 1916 when a young man in the early twenties, the sudden onset of severe low backache led eventually to his discharge from the Army as a case of fibrositis of the back in a man of poor moral fibre. Since then backache and spinal stiffness relapsed and remitted, with the condition gradually worsening until he was seen by us thirty-three years after the onset of the condition. It was at this time that the diagnosis of ankylosing spondylitis was first made. His fixed, bent back and chest expansion of ½ in. made a typical picture.

Ankylosing spondylitis starts insidiously, usually in the lower spine, and the sacro-iliac joints are early affected. Nevertheless, by the time the patient comes to hospital, there is usually limitation of thoracic expansion, measurements of chest expansion at nipple level being reduced to 1 in. or less, the vital capacity significantly reduced by 20–40% of the normal figure for that subject. In a recent enquiry at Westminster Hospital it was found that of 62 patients with ankylosing spondylitis, 46 (74%) had experienced tightness and discomfort in the chest wall on deep inspiration at some time after the onset of the disease. Only 8 (13%) had never experienced these symptoms at any time since the onset of their spinal condition. 8 (13%) had noticed these symptoms only slightly and intermittently. In a few cases these symptoms dominated the picture from the first. In the cases we have seen there has been significant reduction in chest expansion in 3 out of 5 patients in cases of duration

varying from a few months to thirty-three years. It is not a late finding only, it is usually present at the patient's first attendance at our Clinic.

Underlying pathology.—Every thoracic vertebra has eight articular facets—intervertebral superior and inferior right and left, costo-vertebral and costo-transverse (Fig. 1). All these may be affected, though commonly the involvement is a patchy and irregular one. The result is pain and limitation of costal movement in the earlier stages, complete fixity with bony fusion in the late stages of advanced cases (Figs. 2 and 3). Respiration is largely diaphragmatic (Figs. 4, 5 and 6). The patient complains of stiffness and immobility of the chest wall, inability to take a deep breath, and not infrequently tenderness in sternum and/or ribs. This last complaint was present at some stage in two-thirds of our 62 patients. Inflammatory changes in the spine may be referred to points lower in the chest or to the flanks and abdomen, simulating the girdle pains of other diseases. Exertional dyspnœa may be caused, though other factors, e.g. hip involvement, may limit exercise capacity and render exertional dyspnœa unlikely, or impossible. It is not uncommon for thoracocervical kyphosis to give a hang-dog appearance to these patients, but this factor is absent in many, and probably does not affect vital capacity greatly unless this deformity is marked. In 7 normal students Dr. Keith Robinson found little effect on vital capacity by taking estimations in equivalent positions of kyphosis (Table I). Such deformity, if marked, will certainly play a part in restricting thoracic movements and diminishing vital capacity, but this factor probably is not an important one in the average case as compared with involvement of rib or intervertebral articulations.

TABLE I

Subject	Vit. cap. in c.c.	90 degrees flexion of trunk	Full cervico-dorsal flexion	Half-way position
J. B.	5,300	5,200—98%	4,600—87%	5,000—94%
A. D.	5,000	4,900—98%	4,000—80%	4,300—86%
P. G.	4,400	4,200—96%	3,800—87%	4,100—93%
H. C.	5,200	5,200—100%	4,400—85%	
J. B.	3,800	3,800—100%	3,200—84%

A. B.	5,500	5,400—98%	4,500—82%	5,100—93%

Thoracic pain may be a striking symptom in this disease. One man, 37 years of age, was admitted to hospital with a five months' history of aches, pains, stiffness in the lower thoracic spine and across the shoulders. Two months after the onset of these symptoms lumbar pains and stiffness of the back made their appearance, together with a tight constricted feeling in the chest. He felt he could not fill his lungs properly. He was admitted to hospital in great pain, unable to bend his back at all or lie comfortably in bed in any position, and he was unable to take deep inspiratory efforts because of the severe painful constricted sensation in the chest wall. Analgesics gave only partial and temporary relief. Chest expansion was under 1 in. at nipple level, vital capacity 56% of normal. On deep X-ray therapy to the spine, 1,200 r to three ports, the pain abated. Improvement was noted after the second application to each field. After the completion of the course vital capacity had risen to 80% of normal; a few months later to 110% of normal, his chest expansion to 3 in. A second case, a man aged 50, was admitted with pyrexia and severe constricting pain in the chest of four months' duration. He had a history of backache going back four years. The same picture of painful restlessness with inability to find a comfortable position in bed was noted, the combination of stiffness, pain and constricted thoracic sensation producing marked distress and making nursing very difficult. X-rays showed a more advanced spinal condition than in the first case, but relief of the severe symptoms was obtained within seven days of the start of deep X-ray therapy.

In such severe cases with the thoracic discomfort predominating, deep X-ray therapy appears to give greater relief than any other measure.

A third case may be quoted at this point.

A man aged 50, previously well and extremely fit, noticed in August 1948 stiffness of the spine and cough with shortness of breath. Stiffness was most marked in the lumbar region but later involved the neck. He was admitted at this time to a hospital overseas and as he was found to have ankylosing spondylitis was treated on constant bed rest. In October 1948, approximately a month after admission to hospital, sudden onset of pain and dyspnœa occurred due to right-sided spontaneous pneumothorax. Aspiration of air was carried out. As the pneumothorax failed to expand a right phrenic crush was attempted, happily only the sympathetic nerves of the area were avulsed, giving him a right-sided Horner's syndrome and leaving his diaphragm unaffected. He returned to England at the end of the year and came under our care in March 1949. He was a typical spondylitic. There was moderate thoracic kyphosis with the head held rigidly forward. The lumbar spine was flattened and all spinal movements severely restricted. All peripheral joints were normal. He was tender over the last ribs on both sides. His chest expansion was ¼ in. Signs were present of a right pneumothorax. X-rays showed a right pneumothorax with adhesions at the apex; no fluid was present. There was a little old tuberculous infiltration at the left apex. Diaphragmatic movement was full; no rib movement was present. Advanced ankylosing spondylitis was seen in sacro-iliac joints, dorsal and lumbar

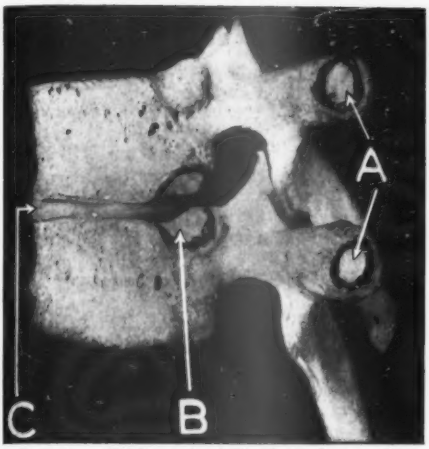

FIG. 1.—Fifth and sixth thoracic vertebræ. A.—Articular facet with ribs. B.—Articular facet of rib with adjacent vertebræ. C.—Intervertebral disc. Involvement of A and B causes pain and fixation of rib on vertebral column.

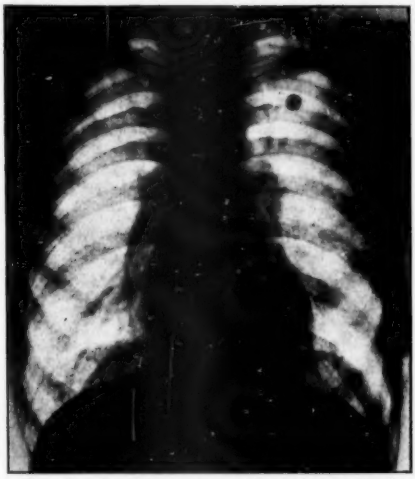

FIG. 6.—Double exposure X-ray in ankylosing spondylitis. Rib movement is slight, diaphragm excursion is normal.

FIG. 2.—Normal costo-transverse articulation with first rib.

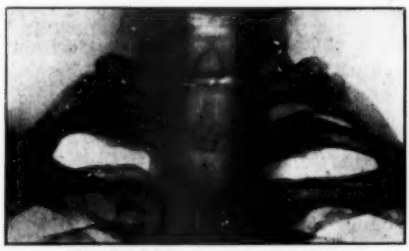

FIG. 3.—The same joint involved in ankylosing spondylitis.

FIG. 4.—Double exposure X-ray in normal subject.

FIG. 5.—Double exposure X-ray in emphysema. Rib movement is not apparent; diaphragmatic excursion minimal.

spines. Vital capacity was 38% (1,700 c.c.). On deep X-ray treatment, accompanied by breathing exercises and the freedom of not only the ward but the entire hospital for the encouragement of full bodily exercise, his spinal condition improved markedly, but the pneumothorax only partially, and now, eight months later, this is still present.

This case-history shows the importance of exercise in general, and breathing exercises in particular. Immobility, particularly in plaster beds or jackets, hastens fusion of the chest wall and lowers the vital capacity markedly, the chest becoming fixed in the position of rest. Advanced cases of ankylosing spondylitis are almost completely dependent on their diaphragm for respiration, and one shudders to think what might have happened had the diaphragm been paralysed in the last case quoted above. If operations are necessary in such cases, the anæsthetist should be fully aware of the dangers, post-operative treatment must be carefully supervised, and early mobility and breathing exercises instituted. Such patients should be the minimum time in bed.

I have had 5 cases of ankylosing spondylitis who had also pulmonary tuberculosis. In each case the spinal condition preceded the pulmonary one. The therapeutic problem is here a difficult one as the two treatments are opposed—rest for the pulmonary tuberculosis, mobility and deep X-rays, postural and breathing exercises for the spondylitis. The maximum mobility possible should be allowed such patients, who on resting feel their spinal condition worsening in fixity, pain and forward curvature. Every effort should be made to prevent spinal deformity by correct posturing; the patient should not be allowed to become bent forward on a pile of pillows. Some substance, such as ACTH or Compound E (Kendall) (Cortisone), known to be effective in ankylosing spondylitis, may help in such difficult cases in the future; at present the combination of the two diseases is a therapeutic nightmare.

In 62 cases of ankylosing spondylitis we have enquired as to increasing incidence of coughs, colds and respiratory complaints. This enquiry has not revealed any particular predisposition to these complaints since onset of the spinal condition.

The symptoms resulting from restricted respiratory movement of the thoracic wall by ankylosing spondylitis are easily distinguishable from the dyspnœa of cardiac or pulmonary disease, the essential differentiating features in ankylosing spondylitis being:

(*a*) Spinal rigidity with absence or diminution of spinal extension.
(*b*) Diminished chest expansion with no physical signs in lungs.
(*c*) Chest is fixed in partial expiration, i.e. the position of rest, rather than partial inspiration as in emphysema or bronchitis.
(*d*) Absence of bronchial spasm and cough.
(*e*) Occasional tenderness on percussion over the sternum, and less commonly the adjacent costal cartilages and the lower ribs.

SUMMARY

Involvement of costo-transverse and costo-vertebral articulations in the rheumatoid process, known as ankylosing spondylitis, causes diminution in chest expansion and thoracic pain, sometimes severe. In the early stages limitation of thoracic expansion is due to pain arising at the costo-vertebral and costo-transverse joints; later bony ankylosis leads to a fixed chest. Spinal rigidity with loss of spinal extension on deep inspiration is a contributing factor. Spinal kyphosis, if extreme, adds to respiratory disability. Thoracic pain and exertional dyspnœa, so caused, may be erroneously attributed to cardiac or pulmonary disease unless other signs of ankylosing spondylitis are noted.

Recherches Kératoplastiques

By JOHN FOSTER, F.R.C.S. and ARTHUR LISTER, F.R.C.S.

Mr. John Foster:

This title was adopted by my co-author and myself as we planned our tour in France to see as much keratoplasty as possible.

We visited Professor Bonnet at the Hôpital Edouard Herriot at Lyons, 120 of whose 3,000 beds are in an Ophthalmic Pavilion. Some plastic operations and a Lagrange sclerectomy were performed. This latter operation is performed with an almost vertical knife-entry, and the sliver of sclera "sawn off" the conjunctival flap with a Graefe knife. Far from being merely a stage in the development of the trephining operation (as many of us imagine here) it is used in preference to the latter and we saw many excellent results from it.

Our next visit was to the Hôpital de l'Antiquaille, where Professor Paufique has a hundred beds. It was here and in several private hospitals in the city that we were privileged to see the Professor perform, besides other operations, some twenty keratoplasties in a single week. In all these institutions the nursing is carried out by réligieuses. This enormous volume of work is only possible because Paufique's practice is purely pathological, refractions being referred elsewhere.

Theatre Technique.

Intense lighting from a scialytic lamp plus a portable searchlight directed from above and to one side are employed in all cases: black towels are used for contrast.

Complete aseptic technique is employed, the surgeon wearing cap, mask, gown, sterile linen bags over the boots, and linen gloves (rubber is judged too slippery). The patient's hair is restrained by a stockinet cap and the eyebrows as well as the eyelashes are removed. Iodine is applied to the skin and a speculum inserted to ensure thorough irrigation of the fornices during lavage.

Keratoplasty.

In all types of keratoplasty a van Lint akinesia and retrobulbar anæsthesia are employed, 20% of ethyl alchohol being added to the scurocaine. A preliminary iridectomy is performed in all cases with synechiæ, a special operation of Paufique's own devising being employed where an oblique trephining of the cornea permits half the disc to be elevated like a trap-door for detachment of anterior synechiæ from an adherent leucoma.

All these measures are antidotes to post-operative glaucoma which, though less frequent than it was, remains the "curse of the grafting classes".

An Arruga speculum is employed and all grafts are finally held in position by egg membrane and by the cruciform sutures described by Zirm. The membrane is cut from the hard-boiled egg by trephine and preserved in alcohol, being dipped in saline before use and nicked here and there at the edge to make it fit better. If egg membrane is not employed, pressure furrows from sutures may persist up to three months in a lamellar graft and a lesser time in the perforating type.

In keratoconus where the graft and cornea are unequally thick, the membrane may have to be omitted and in large lamellar grafts which do not bed down well, direct edge-to-edge sutures (Grieshaber 81/10 needles and Jayle's conjunctival forceps are required) may be employed. One black silk skin suture is inserted afterwards to hold the lids together for four days.

Several donor eyes are available in each case, so that an imperfect graft can be rejected without hesitation. The whole position in this matter, in France, has been revolutionized by the decree 47.2057 of October 20, 1947, which reads: "When in certain listed hospitals death has been certified by two members of the staff after application of suitable tests and the head of the clinic considers pathological or therapeutic interests require it, post-mortem and removal of organs may be performed in the first twenty-four hours without obtaining the consent of the relatives."

This enactment might serve as a model for Great Britain as the work seen in France clearly shows that lamellar keratoplasty will benefit a large number of cases hitherto regarded as untreatable here. The supply of donor eyes excised for neoplasms will be quite inadequate to meet these new demands.

Lamellar Keratoplasty.

This was not only applied to indolent corneal ulcers and active trachoma, and the dystrophies of Haab-Dimmer and Groenouw but also to aphakic eyes, to Fuchs' epithelial dystrophy and corneæ porcelainized by burns, which can then be subsequently grafted by the penetrating method with some hope of success.

The recipient is first trephined with a Franceschetti trephine of 5–10 mm. diameter set to cut at 0·25 or 0·5 mm. according to the depth at which the opacity is judged to lie. Both surgeon and assistant check the verticality of the trephine simultaneously. When the depth of the trephine cut is judged equal and adequate all round, a small elbowed knife is used to start the undercutting. This is continued by retracting the disc with a small double hook as it is cut from the cornea by a Desmarres' scarificateur. Further layers may be removed to ensure a bed free from scar tissue. In one case the final layer could only be removed from Descemet's membrane after paracentesis (nearer the edge of the cornea) to render it more lax. This was one of the most remarkable pieces of surgical craftsmanship I have ever seen. Hæmorrhage is carefully stopped by touching bleeding points with a cautery heated in a spirit lamp. The graft is not cut until the bed is prepared as only then is the thickness of graft required known. The bed must be dry.

Donor eyes are stored in hour-glass-shaped bottles with a little water in the bottom, at 4° C. up to twelve hours for penetrating grafts and up to seventy-two hours for lamellar grafts.

The assistant, using both hands, holds the eye in gauze on a table while the graft is cut. The technique is similar and the disc of the same size as that taken from the recipient eye. It is then placed in position, after dipping in penicillin, and retained as described above.

Penetrating Grafts.

The graft in this instance is usually cut first, with a 5 mm. Franceschetti trephine. It is then dipped in penicillin and placed aside in dry gauze. The pupil centre of the recipient's eye is marked with Indian ink. The 5·1 mm. trephine has a central point which is placed on this to make the initial cut before inserting the sutures. No attempt is made to cut the disc completely through. As soon as the anterior chamber is entered the disc is drawn up at this point and cut away along the line or the trephine mark by an Arruga knife. This instrument leaves few, if any, Descemet tags and tends to cut a larger rather than a smaller opening so the line must be followed carefully.

The pupil is small at the start of the operation but mydricaine is injected subconjunctivally and the placement of the egg membrane delayed until the pupil has dilated past the edge of the graft. In large (7 mm.) grafts pilocarpine is instilled to draw the pupil away from the edge of the graft in the opposite direction.

Tattooing.

In one case where several grafts had failed (in a case of tuberculous keratitis) a dental syringe was used to inject Chinese ink into the substantia propria overlying the pupil. This produced a round, densely black area. There was no reaction when seen two days later.

Apart from the demonstration of the technical details of lamellar grafting and the wide range of cases to which it could be applied and their after-results, the most impressive lesson we learned was the degree of skill and confidence which a gifted surgeon can attain in this operation, given adequate material.

Although Professor Paufique regards lamellar keratoplasty as more difficult than the penetrating to perform, the greater variety of cases to which it is applicable and the fact that the anterior chamber is not opened should render it immediately popular here, but for the limiting factor of donor material.

Our grateful thanks are due to Professor and Madame Paufique, and his assistant, Dr. Hugonnier.

Mr. Arthur Lister

From Lyons we went to Nantes where we spent four days watching the work of Professor Gabriel-Pierre Sourdille. He has some 140 beds at his disposal.

Like Paufique, Sourdille is a first-rate operator whom it was a delight and inspiration to watch. Although he does most of the preparation of his patients himself he gets through long operating lists surprisingly quickly and without apparent hurry. In one session fourteen, mostly major, operations occupied three hours and a half.

Theatre Technique.

Asepsis is scrupulous. The surgeon and his assistants wear rubber gloves—Sourdille always wears English ones. Lighting is by a comparatively dim head-lamp combined with an almost dark theatre and dark towels. This is by design because he considers that a bright light may dazzle and startle the patient, especially during cataract and graft operations. The patient is operated on on the trolley which brings him to the theatre, the surgeon and his assistants being seated.

Keratoplasty.

We watched Sourdille do six grafts; two each of total lamellar, partial lamellar and partial penetrating. The main points in his technique are:

Penetrating.—(1) The pupil is dilated if the graft is to be 5 mm. or less in diameter, but it is contracted for larger grafts, in order to avoid the danger of the pupil border lying opposite the edge of the graft with increased risk of an anterior synechia.

(2) The eye is anæsthetized with cocaine and adrenaline drops and a retrobulbar injection of scurocaine and alcohol (5 to 1) is also given. The object of the alcohol is to minimize post-operative reaction and thus the tendency to a rise in intra-ocular pressure which is the most common serious complication of keratoplasty.

(3) Complete akinesia is achieved by injecting all four recti and the orbicularis with scurocaine and alcohol and some surocaine is injected into the lid margins.

(4) The size of the graft varies from 4 to 7 mm. The most common is 5 mm., though Sourdille says that there may be advantages in making it larger than this. He uses, as a rule, the same trephine for recipient and donor though he admits that this point is arguable and that a slightly smaller graft may adapt itself better to its bed in the cornea. (In my short experience I certainly prefer quite a loose fit of the graft in its bed.)

(5) The graft is cut first, i.e. before touching the recipient's eye. The donor eye which has been preserved since its removal—almost always from a cadaver—in liquid paraffin at 4° C. is washed in saline and held in a piece of gauze in the operator's left hand while the graft is being taken.

Great care is taken to ensure that the trephine is held absolutely vertical to the cornea and for this reason Sourdille advocates that the graft should always be taken from the centre of the cornea. In this context he does not approve of Amsler's method of cutting a graft from behind forwards on the isolated cornea since he feels that it is important to cut both donor and recipient corneæ in the same direction to ensure an accurate fit.

The trephine is carried right through the cornea into the lens to ensure that the graft is completely freed. The graft is then carefully washed and care is taken to ensure that it is free of any pieces of iris or lens. It is then placed in the folds of a dry piece of gauze on which is placed a fairly heavy instrument to prevent its being knocked on to the floor by a hasty movement on the part of the surgeon.

(6) The surgeon now turns his attention to the recipient. Sutures are put into each lid for retraction and held by an assistant. Sutures are also placed in the tendons of the internal and external recti and are held by a second assistant.

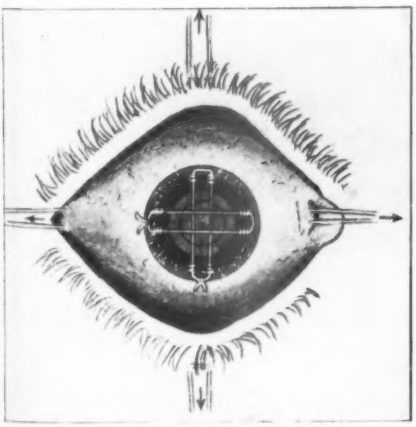

FIG. 1.—Sourdille's crossed sutures.

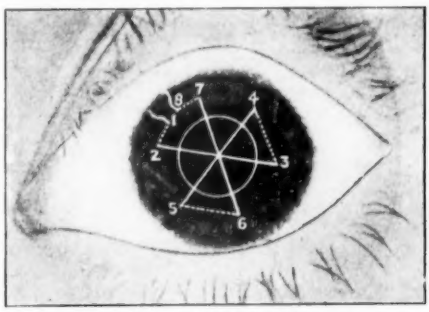

FIG. 2.—Katzin suture.

(7) The disc to be removed is marked with the trephine. Though Sourdille has a special ring for facilitating the accurate centering of the graft on the cornea we never saw him use it. After marking the cornea with half a turn of the trephine he lays the sutures which are to hold the graft in place. His method of suturing varies in different cases and I was not always quite sure why he chose a particular method. He most commonly uses double crossed sutures the bite at each end being purely corneal (Fig. 1).

He used a Katzin suture on one of the penetrating and on one of the partial lamellar grafts (Fig. 2). In the former he also put in two edge-to-edge sutures; this was because vitreous was present in the anterior chamber and he says that one should always employ two or more edge-to-edge sutures in these circumstances. He also sometimes puts a disc of thin rubber beneath the crossed sutures; he does this when there is a tendency for the graft to bulge.

(8) Having laid his sutures he trephines the cornea until the anterior chamber is opened; he then completes the removal of the disc, if necessary, with a rather large pair of double-curved scissors. He prefers this to any other method; there were certainly no tags of Descemet's membrane when he had finished (Fig. 3).

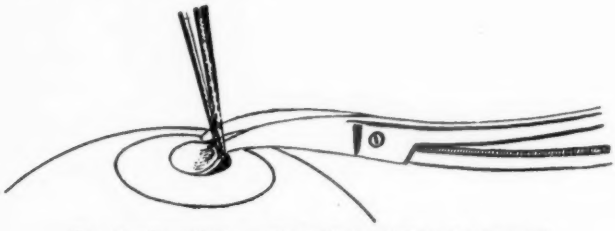

FIG. 3.—Sourdille's method of completing the removal of the disc from the recipient's cornea (penetrating graft).

(9) The graft is then put into its bed and fixed as I have already indicated. Atropine is instilled if the graft is not more than 5 mm. in diameter; if larger no drops are put in, or pilocarpine may be used.

(10) The patient's lids are sutured together and he is double padded.

Lamellar.

(1) The recipient's disc is removed first for two reasons; firstly to give time for any bleeding in the bed of the graft to stop and secondly because if, during the operation, it is found that the opacity is deeper than was at first thought it may be decided to do a penetrating graft instead of a lamellar.

(2) After one or two turns of the trephine the depth of penetration is investigated with an iris repositor. If it is not deep enough it is further deepened with the trephine—not, as in Paufique's technique with the tip of a Graefe knife.

(3) Having got to the required depth the edge of the disc is grasped with a pair of forceps and stripped off with Desmarre's "scarificateur" (Fig. 4).

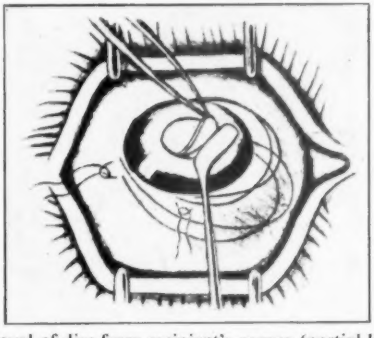

FIG. 4.—Removal of disc from recipient's cornea (partial lamellar graft).

The graft is cut as Sourdille describes in the symposium on keratoplasty which he wrote with Paufique and Offret (Fig. 5).

The graft is fixed in position in the same way as a penetrating graft.

(4) For a total lamellar keratoplasty both the recipient's disc and the graft are lifted in the same way, i.e. a suture is placed in the edge and is used to lift the graft as it is stripped off with the scarificateur in one piece—not, in the case of the recipient's disc, as is described in the book below mentioned (Figs. 6 and 7).

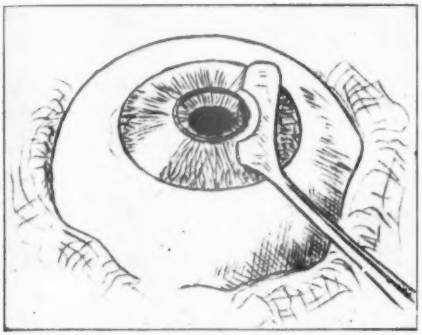

FIG. 5.—Sourdille's method of cutting lamellar graft (partial lamellar).

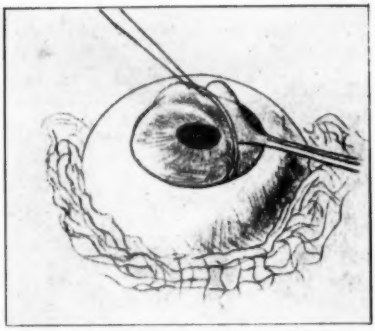

FIG. 6.—Sourdille's method of cutting recipient's disc and graft (total lamellar).

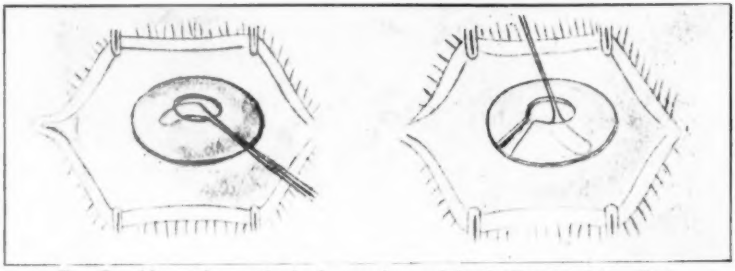

FIG. 7.—Alternative method of removing recipient's disc (total lamellar).

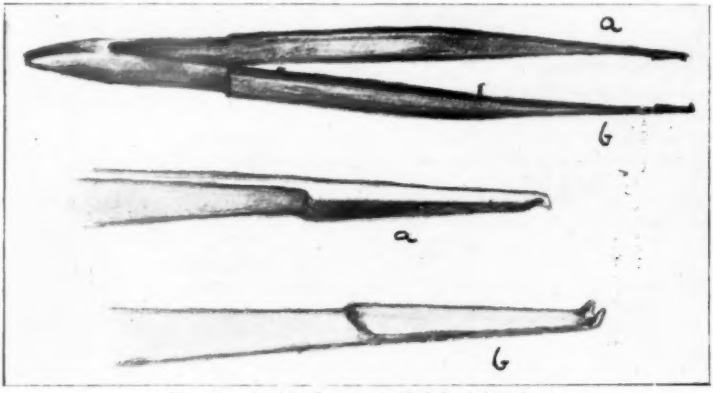

FIG. 8.—Jayle's forceps. (Original drawing).

Great care is taken to stop all bleeding points before laying the graft in position where it is fixed by edge-to-edge sutures.

Jayle's forceps are used by Sourdille as a general purpose instrument—for the conjunctiva, for sutures, for holding the recipient's disc in a corneal graft and so on. They have a "platform" on each blade behind the "one in two" teeth. They are stronger than straight iris forceps but are more delicate than conjunctival forceps (Fig. 8).

Accidental perforation of Descemet's membrane during the removal of the recipient's disc, which happened more than once, made no difference and the operation proceeded. As far as I know Sourdille does not, as a rule, do an intentional paracentesis before placing the graft, as Paufique does.

Notes On Cases

Altogether we saw Sourdille do 10 keratoplasties, 6 *in vivo* and 4 in cinematograph films.

(*a*) *Partial Penetrating.*

(1) For a central scar of unknown origin. A lamellar graft was intended but Descemet's membrane was found to be opaque so it was removed with the trephine and scissors and a penetrating graft put in.

(2) Leukoma adhaerens with vitreous in the anterior chamber. The recipient's disc was removed as usual, the synechia being separated from its under surface. The graft was fixed with a Katzin and two edge-to-edge sutures.

(3) A quiet disciform keratitis.

(*b*) *Partial Lamellar.*

(1) A peripheral graft in a case of severe active I.K.—purely as a therapeutic measure (4 mm.).

(2) A superficial central scar (6 mm.).

(*c*) *Total Lamellar.*

(1) An absolutely hopeless-looking staphylomatous opaque cornea due to I.K.

(2) An equally hopeless-looking scarred cornea following burns.

(3) A case of scarring due to burns in which the total lamellar was a preparatory graft to be followed later by a penetrating one.

(4) A case of band-shaped keratitis due to Still's disease.

We thus saw all three indications for lamellar keratoplasty applied: optical, therapeutic and preparatory.

Discussion

In a short discussion on keratoplasty which we had with Sourdille I gathered the following points:

(1) He gave the impression that keratoplasty is applicable to almost any corneal disease.

(2) Grafts are either optical, therapeutic or preparatory.

(3) *Penetrating* grafts are always optical and should never be used for therapy; also, they should only be employed on quiet eyes, when there is a fair amount of normal corneal tissue present and when there is not excessive vascularization, especially if it is superficial.

(4) *Lamellar grafts* may be optical, therapeutic, or preparatory, and they may be employed successfully in the presence of active inflammation, e.g. disciform keratitis and immediately after burns.

It is suggested that a total lamellar graft should be employed in the first few days after bad chemical burns. This is rational, but I understand that Paufique has not found it so successful as Sourdille. Lamellar grafts are also used therapeutically in cases of chronic and recurrent simple herpetic keratitis and in serpiginous ulcers—it will be remembered that Black reported a remarkable instance of the latter at the last meeting of the O.S.U.K. though he used a penetrating graft.

As preparatory grafts they may be used in badly scarred or vascularized corneæ, and in band-shaped keratitis in preparation for penetrating keratoplasty—such grafts are usually total.

A lamellar graft is also suggested for Fuchs' dystrophy and for rosacea keratitis but opinions differ on their success in such cases.

It is noteworthy that glaucoma has not been found to be the menace in lamellar keratoplasty which it is in penetrating. It used to be routine to trephine the eye at the end of the lamellar operation but this has now been discontinued.

Finally it is worth while mentioning a point which struck me, namely the absence of special devices such as punches, nibblers for tags of Descemet and such like. Simplicity was the hall-mark of the surgery we saw.

For the reproduction of Figs. 1–7 I gratefully acknowledge permission granted by the authors and publishers of "Les Greffes de la Cornée," a report presented to the Société Française d'Ophtalmologie by Paufique, Sourdille and Offret and published by Masson et Cie, Paris, in 1948.

Mr. H. E. Hobbs said that he had spoken to Dr. Paufique in Lyons on the subject of the prophylaxis of post-operative hypertension and he had been told that this complication was now much less feared in Lyons than formerly. Trephine operations were no longer employed as a routine measure, but he had seen Dr. Paufique perform a paracentesis with the keratoplasty on several occasions.

Mr. A. McKie Reid asked whether in these cases the Wassermann test had been carried out on the donor.

Mr. Lister said that he did not think it mattered. He could not believe that the spirochæte would survive for forty-eight hours under the conditions in which the donor eye was preserved.

Dr. E. C. B. Ibotson asked what percentage of cases became opaque after this operation.

Mr. Lister replied that the prognosis varied according to the condition for which the operation was done. In some cases, such as familial dystrophies, there was 100% chance of success; in interstitial keratitis about 50% chance, and in severe burns the chances were very much less.

Mr. Foster said that they had found it difficult to get a clear-cut answer to this question of success percentages, but of perforating grafts about 45% appear to show varying degrees of visual improvement.

Lamellar grafts are performed in many cases for therapeutic or tectonic reasons, where no immediate visual improvement is expected, with a very high percentage of structural success. When employed to improve vision they are applied to a wider selection of cases than the perforating type and the percentage of visual successes would appear to be lower.

Mr. B. W. Rycroft said that there was one precaution to bear in mind with a lamellar graft. It was difficult beforehand to assess the depth to which a scar penetrated in the cornea. One worked on a diffuse nebula, and very often started off with the idea of doing a lamellar graft and had to abandon that procedure, before finishing, for a total graft.

Mr. Foster said that it was, on occasion, very difficult to judge the depth of the lesion but when this was pointed out to the French surgeons they replied: "If the lesion is deeper than anticipated you can either convert the operation into a penetrating graft or perform a penetrating graft later."

[*December* 8, 1949]

RETROLENTAL FIBROPLASIA

Mr. P. McG. Moffatt: *Clinical Aspects of Retrolental Fibroplasia.*

No paper has so far appeared in this country under the title of Retrolental Fibroplasia. I can find only one report of a case, which Galloway showed at a clinical meeting of this Section in February 1948 at Birmingham (*Proc. R. Soc. Med.*, **41**, 724). Practically all the references are to be found in the American journals in which there is a very considerable volume of literature following the original report of Terry (1942a). This was a preliminary report under the heading "Extreme prematurity and fibroblastic overgrowth of persistent vascular sheath behind each crystalline lens".

Five other cases were cited, in which the findings were similar. All were premature, weighed 3 lb. or less at birth and had no evidence of hereditary factors.

To this clinical description, which had not previously been reported, can be added photophobia, shallow anterior chambers, opacities in the cornea and fine vessels visible on the retrolental membranes, persistence of the blue-grey colour of the iris which he called the "Fœtal blue colour", and failure to develop normal iris pattern. As the disease progresses the shallowness of the anterior chamber increases, posterior synechiæ form, and the affected eyes do not grow normally, becoming microphthalmic and the corneal diameter less than normal (this last is a point in differential diagnosis from retinoblastoma in which the cornea is unlikely to be smaller than normal). Glaucoma usually without hydrophthalmos, and cataract frequently develop. Anterior synechiæ form, the opacities in the cornea increase and the globe shrinks. The dentate processes mentioned in the original account were subsequently recognized by Terry as ciliary processes, narrowed and elongated, sometimes lacking pigment at their tips. Retinal detachment is a frequent complication.

To this condition, believing it to be due to a fibroplastic overgrowth of embryonic remains in the interstices of the vascular network of the posterior tunica vasculosa lentis, Terry (1942b) gave the name "Retrolental Fibroplasia", on morphological grounds so that it should be free from causal suggestions. In course of time he came to regard a great many developmental abnormalities as part of the disease and believed they arose from persistence of the hyaloid system, the presence of embryonic connective tissue behind the lens, or persistence of the fœtal character of the vitreous. The degree of fibroplasia could vary very widely in extent. The condition is rarely found in full-time infants and is usually unilateral when it occurs.

Terry was the first to observe the condition develop after birth in three cases, the postlental membrane began to form at the extreme periphery of the lens and covered the whole of the posterior surface within two weeks.

Owens and Owens (1949a) and Gilger (1949) found an incidence of about 7% in premature infants weighing 4½ lb. or less at birth. From Boston (Terry, 1945a; Clifford and Weller, 1948) figures are quoted as high as 23% for infants under 3 lb. The incidence appears to vary in different places, and even in different nurseries in the same city (Terry, 1945b). There is some evidence that the disease increases inversely with the birth-weight. Whereas the bilateral cases have increased, there is, according to Reese, no increase in incidence in the unilateral cases.

The prognosis in the fully established condition is bad. The eyes become blind and shrunken in many cases, but Terry found that in a small number where the eye grew normally the membrane behind the lens retrogressed and gaps appeared in it. The vision, however, remained very poor on account of associated changes in the retina.

Angiomatous lesions of the skin were reported in 15% of one series of cases (Reese and Payne, 1946a), and in 20% of a series of 100 cases by Terry in 1948. Mental retardation was not found to be more prevalent than in any series of premature infants, but Krause considered that most cases, if examined after the age of 4 years, would be found to be mentally retarded. He believes that the disease is due to aplasia of the anterior neural ectoderm and that retrolental fibroplasia is only a part of a wider failure to develop the anterior portion of the central nervous system.

Owens and Owens observed a large series of premature babies from birth and state that the first changes are dilatations on the retinal blood-vessels followed by swellings in the periphery of the retina and massive exudates going on to detachment. In their opinion the post-lental membrane is formed by the fusion and organization of the retinal folds behind the lens, and the vessels seen in the membrane are derived from the retinal vessels and not from a persistent hyaloid system as was thought by Terry. Out of the series 9 cases of this condition were found and observed. None had any evidence of persistent hyaloid or tunica vasculosa at birth, the eyes appeared to be normal. The disease manifested itself between the 2nd and 4th month of post-natal life.

Gilger (1949) examined a series of 229 cases of premature infants and found a similar incidence, no case occurring in an infant weighing more than 4 lb. at birth. There was no statistical evidence to show that race, age, parity, ante-natal bleeding, virus infection, or chronic illness, tuberculosis or syphilis in the mother, had any influence on the ætiology. Nor did she find that the cause of onset of premature labour, or the post-natal management of the infants were factors in the ætiology. Males were more frequently affected than females, and it has been suggested that the disease might be sex-linked as in one series of 150 cases, 95 were males (Bakwin, 1946). Gilger could form no conclusions from her series as to the role played by vitamin A. Warkany and Schraffenberger (1946) showed that rats developed a similar condition if the mothers were on a low vitamin-A diet. Jackson and Kinsey (1946) repeated this work with the same results but doubted whether the vitamin-A levels fall as low as those in experimental animals.

Gilger did not find that the increased incidence of the disease was related to increased survival rate of premature infants. Reese and Payne (1946b) consider that the lesion is due to persistence of the primary vitreous, with or without hyperplasia and that it is present at birth. Reese criticizes the concept of Krause on the grounds that the eye signs are not a dysplasia of the retina but fibrous tissue in the vitreous, and maintains that remains of the hyaloid artery are present which would not be expected in a dysplasia. He also disagrees with Krause's interpretation of his finding of mental retardation in his cases examined after the age of 4 years, and states that if cases of hydrocephalus are excluded, only 30% show mental retardation, a figure which might reasonably be expected in any series of premature infants. He also criticizes the work of Owens and Owens who state that there are no persistent embryonic structures at the onset, on the ground that these lie at the very periphery of the fundus and may have been missed unless the infant were examined with pupils fully dilated and under general anæsthesia. Reese recognizes two clinical entities: (1) Persistence of the primary vitreous with hyperplasia occurring in full-term infants of normal development and usually affecting one eye only. (2) True retrolental fibroplasia in which only a portion of the primary vitreous remains in the region of its base, and is bilateral.

Exposure to light was early considered as a possible factor in the ætiology but it has been shown by Hepner and others (1949) that the disease develops even when the eyes are covered until a weight of 4½ lb. has been attained.

It is rare for more than one case to occur in a family except in twins either identical or fraternal. Terry (1948) considered twinning a factor only in so far as it is a common cause of prematurity. Others have suggested that the disease is due to a low-grade infection of the uveal tract. It will be seen that opinions differ widely as to the cause of the condition, when it starts, or from what tissues the membrane is derived.

The differential diagnosis is from retinoblastoma, cataract, and intra-ocular infection leading to cyclitic membrane and pseudo-glioma.

Treatment by operative measures is most unsatisfactory. The lines of attack have been: (1) Needling the lens and cutting a trap-door through the opaque membrane. (2) Dragging out the opaque tissue by the posterior route and cutting it off. Terry considered this was dangerous as portions of ciliary body would almost certainly be pulled out along with the membrane. On the other hand Reese has operated on 11 cases and claims improvement in 3. He says that this method is only suitable in his first type of case. I have tried needling in two cases and found the operation difficult because of the shallowness of the A.C., and the lens does not absorb readily. One case I needled five times and still the greater part of the lens remained after six months. This child is now in a Sunshine Home and I have recently had the opportunity of examining the eyes about a year after the last operation. The pupil is filled by the calcified remains of the lens to which the iris is adherent. There is doubtful perception of light but this also applies to the other eye which was not needled. Both eyes are microphthalmic.

It has been suggested that some cases in which needling of cataracts in infants has failed might also have retrolental fibroplasia.

In view of the difficulty of achieving any useful result by operative measures, Terry suggested that it might be wiser to wait upon events as some cases improve spontaneously. Radiotherapy with a view to closing the blood vessels in the membrane and also to inhibit the growth of the fibrous tissue, has been found to be valueless.

Owens and Owens (1949b) applying the facts learned from experiments with chicks, viz. that high doses of vitamin A and iron inhibit the availability of vitamin E leading to encephalomalacia, studied three groups of premature infants. The first group were treated in the usual way with high protein diet, high vitamin A and iron intake. The incidence of retrolental fibroplasia was the usual figure of 12 to 25%. The second group were given a new water-miscible vitamin E preparation and less vitamin A and less iron than the first group. No instance of development of the condition was seen. The third group in whom the disease was just becoming apparent were treated with addition of the vitamin E preparation and reduction in vitamin A and iron intake, and retrogression or cure of the disease resulted. If this work is substantiated it will mark one of the major advances in the prevention of blindness.

I have had under my care 6 cases, 2 (twin brothers) have been available at this meeting and I have drawings of the eyes of another. The remaining 3 are in Sunshine Homes.

In order to obtain some idea of the incidence of the disease here I have inspected the records of all children in the six Sunshine Homes in this country, and, by kind permission of the National Institute for the Blind, have examined personally every case in which the diagnosis of retrolental fibroplasia had been made or could be suspected.

Out of 119 children being cared for in the 6 Sunshine Homes at the time of the investigation there were 12 cases in which the diagnosis of retrolental fibroplasia could be made with reasonable certainty, two others were doubtful. The first, male, aged 2 years was nine weeks premature and weighed 2 lb. at birth, the right eye had been enucleated and reported on pathologically as pseudo-glioma, the left had posterior synechiæ and an opaque membrane behind the lens, no other information could be obtained. The second child, female, aged 2 years 5 months, ten weeks premature, weighing 2 lb. at birth, developed opaque membrane behind both lenses and posterior synechiæ during the 3rd month whilst suffering from a virus infection of the gastro-intestinal tract. It was felt that this case was due to an infection although Gilger includes a similar case in her series.

Of the 12 cases, 7 were girls and 5 were boys, prematurity varied between twelve and eight weeks, average was nine weeks. Birth-weight varied between 3 lb. 8 oz. and 2 lb. 6 oz. Only 4 were less than 3 lb. There were 2 sets of twins—4 cases, one survivor of twins, and one the sole survivor of triplets.

The age at which the disease was first noticed was recorded as 2 months in two cases, 3, 5, 10 months respectively in three cases and "uncertain" or "probably from birth" in the remainder.

The youngest child at the time of examination was 1 year 8 months and the oldest 5 years. The average age was 2 years 9 months. Three were regarded as mentally retarded by their teachers, but severely retarded cases are not accepted by the Homes. In no case was there any history of blindness in the parents. In one case there was maternal bleeding three months before birth, and the mother of one case had taken large doses of quinine at the 2nd month of gestation. Otherwise the pregnancies had been recorded as normal. No details of the post-natal management were available. All the cases were in an advanced stage of the disease and the early signs had been obscured by secondary changes. Three cases

had severe corneal scarring, 1 case was buphthalmic in one eye, the remainder were microphthalmic in varying degrees. Posterior synechiæ were frequently found as also remains of anterior pupillary membrane. Definitely raised intra-ocular tension was found in one child in both eyes which were microphthalmic. In every case where it was possible to see through the pupils a greyish membrane or mass could be seen immediately behind the lens, though it did not obscure the fundus reflex completely in all cases. Five cases are awaiting admission to the Homes, of these 3 are boys and 2 are girls. One of the boys, in whom the defect was noticed at 6 months, weighed 4 lb. 3 oz. at birth and has a twin sister unaffected.

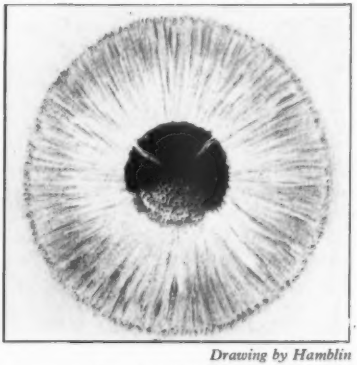
The diagnosis of retrolental fibroplasia is being made more frequently in this country but the numbers do not as yet approach anything like the incidence reported in America, where it is regarded as one of the major causes of blindness in infants.

I would like to take this opportunity of pleading for some machinery to be set up for the systematic examination of the eyes of all prematurely born babies during the first 6 months. It would also be helpful if more detailed notes were made concerning family history, the pregnancy, the post-natal management, the ocular history as well as the clinical findings when these cases are brought to hospital.

My thanks are due to the National Institute for the Blind for permission to visit the Sunshine Homes and examine the cases and records, to Dr. C. T. Potter and to Dr. J. K. Martin for details of the cases shown here:—

D. R. and A. R., male twins, born 17.1.49. Pregnancy normal. First children of young parents. No family history of blindness. Born 8 weeks prematurely. Birth-weights:—D. R. 2 lb. 12 oz., A. R. 2 lb. 8 oz. There was one placenta and chorion.

D. R. developed conjunctivitis at 2 weeks, and had a course of penicillin drops.



Both became rather anæmic. D. R. Hb 66%. A. R. 52%. Treated with iron. Discharged from hospital at 8 weeks weighing—D. R. 5 lb. 7 oz., A. R. 5 lb.

A. R. was admitted to the Evelina Hospital on 20.7.49, at 6 months old, for strangulated hernia. The parents had not noticed anything wrong with the children up to that time. Whilst in hospital it was noticed that A. R. had a roving nystagmus, microphthalmos, and a grey reflex in the pupils. The twin brother was then got up for examination and found to have a similar condition of the eyes.

Neither child attempted to follow a light or take hold of objects. They seem to be aware of a bright light, and a very faint reaction of the pupils can be obtained.

The irides have retained their fœtal blue colour, with lack of iris pattern. Well marked remains of persistent pupillary membrane are present in all four eyes. A grey membrane, in which one or two fine vessels can be made out, can be seen behind the lens in each eye.

The drawing shows the anterior pupillary membrane, the lack of differentiation of iris pattern and the grey reflex from the pupil (Fig. 1).

Drawing by Hamblin

FIG. 1.—Case D. R.

(Cases D. R. and A. R. were shown at the Section of Pædiatrics on *October* 28, 1949, *see* p. 235.)

A. F. C., 3 years old. Birth-weight 5 lb. 12 oz. Born one week prematurely, normal delivery.

This child was brought up to hospital when 11 months old. Examination under general anæsthesia showed whitish membrane behind the lower half of the lens and a grey mass in the vitreous behind it in each eye. The diagnosis was "Bilateral remains of the posterior vascular sheath of the lens".

He has been observed at intervals and appears to have enough vision to be able to avoid knocking into large objects.

The drawings were made very recently and illustrate the present condition so far as this can be reproduced in drawing (Figs. 2 and 3). The retrolental membranes are seen in the lower halves of the pupils, some fine vessels course over them. The atrophic retinæ are depicted as seen above the membranes. Very few retinal vessels could be made out and there were round or oval patches of degeneration. The lower parts of the retinæ were detached.

FIG. 2.

FIG. 3.

FIGS. 2 and 3.—Case A. F. C.

Both eyes are microphthalmic. The right eye has an ill-defined iris pattern and some strands of persistent pupillary membrane. The iris pattern in the left eye is better developed.

Mr. Eugene Wolff (*From the Institute of Ophthalmology*): *Pathological Aspects of Retrolental Fibroplasia.*

Reese and Payne, Krause, Owens and Owens, and a number of others have each added some new facts to this disease entity. There are, however, a number of points that still seem obscure, the main ones being the nature of the retrolental vascular tissue, the cause of the retinal detachment which in a typical case accompanies the disease, and the curious usual time of onset—namely within the first six months after birth.

To understand retrolental fibroplasia from a pathological point of view it is essential I think to compare and contrast three conditions.

(1) Remains of the posterior vascular sheath or hyperplasia of the primary vitreous (Reese).
(2) The usual type of pseudo-glioma.
(3) Retrolental fibroplasia (Terry). Congenital encephalo-ophthalmic dysplasia (Krause).

(1) *Remains of the posterior vascular sheath or hyperplasia of the primary vitreous (Reese).*—This condition has of course been known a long time and there is a huge literature to which Treacher Collins and Parsons have made notable contributions.

Pathological anatomy: Here we find a saucer-shaped or pyramidal mass at the back of the lens. It is thickest in the centre and thins out towards the periphery where it may be absent, allowing a red reflex to be obtained in the living (Reese). The mass consists of connective tissue, cells and fibres and contains a varying number of vessels. Running forwards into the apex of the pyramid is (usually) the remains of the hyaloid artery. The posterior lens capsule may be intact or missing. In the latter case the fibrous tissue passes through the gap, the capsule at the edges being as a rule wavy and thickened. The lens itself is usually clear at first but may become opaque later. The retina here is not detached. The condition is present at birth and is most often unilateral. Pathologically therefore it is very different from the two other conditions.

(2) *The usual type of pseudo-glioma.*—This arises as a metastatic uveitis or retinitis and occurs as a rule in children of about 2 years. I would draw special attention to the fact that the signs of iridocyclitis in the anterior portion of the eye, that is the slight injection, the keratic precipitates and perhaps a synechia or two *come at the beginning of the ocular disease.*

Pathological anatomy: Here the anterior part of the eye up to the pars plana is usually almost normal; it is in the posterior portion that the main changes are seen. The retina is totally detached and it resembles a convolvulus flower. Posteriorly it usually forms a strand running forwards from the disc. I would emphasize that the detachment ends at the ora serrata. The retina is greatly thickened, a thickening which (again I would emphasize the point) goes right up to its site of attachment. It is also much altered. The funnel formed by the detached retina is filled by a vascularized connective tissue, and blood vessels can be seen to pass from the detached retina into the central strand. This central connective tissue reaches to the back of the lens and is continuous with the cyclitic membrane which is always present (Fig. 1).

The cyclitic membrane may be in any of the four stages usually described but as a rule consists of a vascularized connective tissue into which the clear and pigmented cells of the pars plana of the ciliary body have proliferated. This cyclitic membrane is attached to the retina and vessels pass out of the latter into the cyclitic membrane.

The cyclitic membrane is situated in the anterior angle between the detached retina and the pars plana. It is not well known that in the posterior angle between the detached retina and the pigment epithelium a vascularized pigmented mass often grows backwards from the junction of the ciliary body and the choroid at the ora serrata. It may be adherent to the outer aspect of the retina or to the pigment epithelium or to both. It goes through all the stages of the cyclitic membrane in front of the retina and indeed may be called a *retro-retinal cyclitic membrane* (Fig. 1).

The subretinal space is filled with a coagulated mass staining red with eosin and speckled with cholesterin crystals, which may be quite free from cells but usually contains desquamated degenerating pigment epithelial cells and fatty granular cells (ghost cells of Coats).

(3) *Retrolental fibroplasia (Terry). Congenital encephalo-ophthalmic dysplasia (Krause).*—It is of great importance to note that Owens and Owens by examining premature babies from birth found that a retinal detachment starting at the periphery preceded the retrolental membrane and the posterior synechiæ. They also established that all visible remains of the hyaloid system disappeared early in post-natal life.

Pathological Anatomy: Superficially a section of a typical case of retrolental fibroplasia resembles that of a pseudo-glioma. There is a complete detachment of the retina with a stalk posteriorly and a folded thickened retina anteriorly; there is the subretinal fluid staining pink with eosin and there is or *may be* a vascularized membrane behind the lens. But on closer inspection important differences are seen.

It seemed to me that the first problem to solve was to try and establish the nature of the retrolental membrane. Terry thought it had to do with the hyaloid system of vessels or the primary vitreous. But grave doubt was thrown on this hypothesis when Owens and Owens found that all visible remains of the hyaloid system disappeared early in post-natal life. In many of Krause's cases also there was no membrane at all.

Actually the membrane consists of vessels, which are usually capillaries, and connective tissue fibres which are exceedingly fine, the whole looking like embryonic tissue. But there can be little doubt that it is a cyclitic membrane! In the first place a cyclitic membrane is

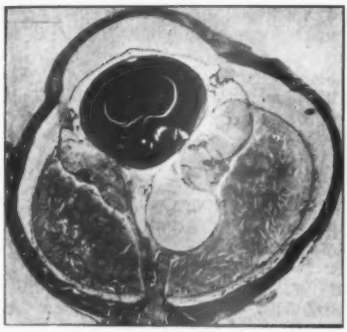

FIG. 1.—Pseudo-glioma. Retina completely detached and thickened right up to attachment at ora.

FIG. 2.—Retrolental fibroplasia (×26). (Mr. Gimblett's case.)

FIG. 3.—Retrolental fibroplasia. × 93. Note that detached retina is attached to pars plana by ciliary epithelium.

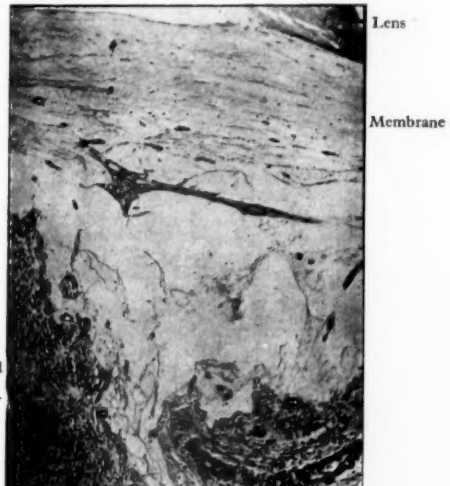

FIG. 4.—Retrolental fibroplasia. × 43. Note retrolental membrane consists of connective tissue, vessels and proliferated clear cells of ciliary body.

by far the commonest cause of a pathological vascularized tissue behind the lens and very good reason must be produced in any given case to prove that it is not (Figs. 2 and 4). Here the membrane consists not only of vessels and fibres but of proliferated epithelium which can quite easily be traced to the ciliary body. Also the membrane as observed clinically appears to develop from the periphery. Only, I would suggest that in retrolental fibroplasia the cyclitic membrane is produced by a very much milder toxin than that in a pseudo-glioma above described.

This is further shown by the fact that I have found only the clear cells of the pars plana growing into the membrane and not the pigmented ones as well. A retro-retinal cyclitic membrane has not been seen. Now a cyclitic membrane signifies inflammation. Actually the signs of inflammation are exceedingly slight but that inflammation does supervene is shown also by the posterior synechiæ which often appear during the course of the disease.

Having established this fact the next was to look for a cause for this mild iridocyclitis. A probable cause was to hand in the presence of the retinal detachment; for we have all had cases of retinal detachment returning after months or years with a ring synechia. Fuchs showed that the reason for this was that the subretinal fluid became toxic and if injected into the eye of an animal could produce an iridocyclitis. *This type of iridocyclitis usually supervenes months or even years after the detachment;* but it is also important to mention that it may never occur.

The next step was to look for the cause of the retinal detachment. This I think is in a typical case to be found in the remarkable difference between the appearance of the detachments in pseudo-glioma and retrolental fibroplasia *in their anterior portions.* In pseudo-glioma the retina, as mentioned before, is thickened right up to its attachment at the ora serrata; in retrolental fibroplasia it usually terminates in a thin portion which looks like the clear cells of the pars plana and is attached at varying distances along the pars plana (Figs. 2 and 3). Krause tells us that in a number of his cases the detachment went right up to the first ciliary process. Now the clear and the pigmented cells of the pars plana unite at about the third month of intra-uterine life and this union is very firm. Hence retinal detachments normally end at the ora.

The meaning of the fact that the detachment continues on to the pars plana is most probably that there has never been proper union between the clear and pigmented cells. Later, one would suggest, a true detachment takes place by fluid collecting between the two layers and gradually spreading backwards.

The above is an account of a typical case. But the abnormality of the retina may be present in a great many other forms. Thus the detachment may be present in its posterior part only or there may be folds in it forming a septum and so on.

It would seem then that in a typical case the course of events is as follows:

A "noxious stimulus" reaches the embryo very early, probably in the first few months of intra-uterine life. Its effect on the eye is primarily on the retina which remains non-attached in part or as a whole. (The noxious stimulus may affect other parts of the organism especially the brain as pointed out by Krause, hence his name for the disease—Encephalo-ophthalmic dysplasia.) Fluid collects under the retina and a real detachment is produced which gradually becomes total. This may give rise to a mild uveitis which is responsible for the retrolental membrane and the posterior synechiæ *when these are present.*

My thanks are due to Mr. Peter Hansell, Dr. Norman Ashton, and also Mr. McNeil.

Mr. C. L. Gimblett : *Retrolental Fibroplasia*

Child aged 1½ years.

This baby was first brought to see me on January 2, 1948, when he was 6 months old. His mother had had five previous miscarriages and this child had been 9 weeks premature and weighed 2½ lb. at birth. Before I saw him the child's mother reported that he did not recognize her. He had nystagmoid movements since birth and mother noticed at 4 months that his sight was defective. She felt, however, that he always had perception of light and that this has improved considerably.

Mr. E. Wolff, who saw the case with me, agreed that there might be present bilateral retinal gliomata and that it would not be safe to leave the child without investigation. So on January 6, 1948, the left eye was removed and Mr. Wolff has described the microscopic appearances.

Neither the child nor his mother showed any abnormality in red or white blood cell counts or colour indices. In both, Wassermann and Kahn tests were negative. The right eye—on dilating the pupil—shows a good red reflex except on the temporal side where it is obscured by a whitish opacity spreading forward from the ciliary region *behind* the lens.

On the nasal side there is a retinal detachment.

From the first the child has shown a complete absence of any pain and as time has gone on he has developed normally and is now walking well.

About April 1949 the iris adhesion which is now to be seen at 9 o'clock was first noticed.

I could not accept the responsibility of telling the mother that another pregnancy would be free from risk of a similar tragedy.

Mr. A. J. Cameron: *Ocular Defects in Premature Twins*

The female monovular twins shown were born prematurely at the 6½ month. One (J.) weighed 2 lb. 11 oz. and the other (M.) weighed 3 lb. Such difficulty was experienced in keeping them alive in oxygen tents that they were 4 months old before doubt was expressed as to their ability to see.

On examination at that time: M. had partially opaque corneæ; anterior synechiæ of the pupillary membrane; opaque lenses; no fundus reflex and marked nystagmus. J. had in the right eye the same condition. In the left the lens was clear with a persistent, posterior, vascular capsule. Nystagmus was present in this case also. In both M. and J. there was practically no anterior chamber.

There would appear to be a current belief that a true retrolental fibroplasia has a free pupil, but I feel sure that this is not a necessary feature. Terry (1946, *Journal of Pædiatrics*, **29**, 770) makes no mention of this point but stresses two points which are very definitely present in these cases, namely the prematurity of the children, and the absence of other abnormalities. One admissible exception to this would appear to be angiomas in the skin and, for what it is worth, each of those children has a nævus, one beside the ear and the other child has one on her wrist. A free pupil has not been mentioned as a necessary feature in the many cases of Terry's syndrome recorded in America.

I am not able to give any opinion as to the condition of the retinæ in either case so that whether or not any of the variations which have been described, such as dysplasia of the retina or hyperplasia of the primary vitreous, are present I cannot say. It can be seen that the children are in excellent health, and appear of normal intelligence. They are now about 3 years old. There is no history of the mother having had any particular illness during the period of gestation.

Many cases which previously have been labelled "pseudo-gliomas" may have been of this type. Since the original examination there is no doubt whatever that the degree of corneal opacity has very much increased and, to-day, so much so that the details behind the cornea can only with difficulty be seen. This is particularly marked in the child (M.) with both corneæ affected, but also holds for the other child (J.), to a lesser degree, in which originally only the one eye showed any marked corneal opacity.

Mr. Norman Fleming: *Retrolental Fibroplasia in Monovular Twins*

In this case of twins, almost certainly monovular, all four eyes were blind.

The mother, aged 37, was married in 1935 when she was 23 years of age. She had abortions in 1937 and twice in 1940, a premature child who died in 1941: in each case the blood pressure was raised. In 1944 a boy was born after medical induction on account of swollen ankles and high blood pressure: this child is alive and well.

In 1945, the twins were born at 33 weeks as the result of spontaneous premature labour and each weighed 3½ lb. The mother had not felt well from the beginning of pregnancy; she suffered from backache and albumin was found in the second month. She was kept in bed at home and subsequently remained in hospital for nine weeks following delivery, in order to breast feed both infants. They were brought to me and found to be blind when aged 3 months.

The mother gave no history of any infectious fever. Her eyes had not been examined during pregnancy but she had not experienced any loss of sight; the fundi were found to be normal and vision 6/5 right and left. Both parents had negative W.R. The mother is Rhesus negative and has a blood urea of 42. E.S.R. 11. R.B.C. 4 9 m.; Hb 87%.

On superficial examination of the twins, all four eyes gave the impression of a glioma of the retina but on closer examination it was found that the pupils were inactive, that it was impossible to find any normal fundus around the "growth" in any eye and that transillumination gave no definite sign of a tumour at any point.

I took the babies to see Mr. E. Wolff and we decided to remove one eye for diagnosis; I am indebted to him also for his examination of the eye after removal.

The eye is a very small one, measuring only 12 mm. from front to back and 11 mm. transversely. The retina is detached and very atrophic. The detachment does not reach to the ora serrata thus differing from the typical case described by Wolff at this meeting. Also there is no retrolental membrane; but the clear cells of the ciliary body are partly detached and are proliferating. The choroid is largely atrophic and there are numerous colloid bodies on Bruch's membrane. Posterior synechiæ are present.

Both twins were found to be suffering from a severe achromatic anæmia for which they were treated for some time, but, the eyes being quiet and no other pathological condition being found, they were sent to the Sunshine Home. They are there now, and are, I understand, in good health.

Dr. V. Mary Crosse

In the City of Birmingham there have been over 5,000 premature births (5½ lb. or less at birth) since January 1945. Of these 4,000 have been followed to the age of 1 year and only 4 cases of retrolental fibroplasia have been found. This gives a case incidence of 0·1 % of all premature babies, 0·8 % of babies under 4 lb. and 4·2 % of babies under 3 lb. Of the 4 cases 2 were binovular twins. The following particulars may be of interest:

Place in family: 1st pregnancy (1 baby)
3rd pregnancy (3 babies)
Maturity: 32 weeks (2 babies)
30 weeks (2 babies)
Ante-natal complications: None
Season born: May (3 babies)
August (1 baby)
Type of birth: Normal vertex (2 babies)
Breech (2 babies)
Birth asphyxia: Present (2 babies)
Absent (2 babies)
Air entry: Poor in all cases
Body temperature: Well maintained in all cases
Œdema: Present (2 babies)
Absent (2 babies)
Jaundice: Mild (3 babies)
Absent (1 baby)
Cyanotic attacks: Severe (3 babies)
Slight (1 baby)
Anæmia: Severe (1 baby) (Two transfusions given)
Absent (3 babies)
Wassermann: All negative
Rh factor: Mother positive (2 babies)
Mother and babies negative (2 cases)
Skin nævus: Present (1 baby)
Absent (3 babies)
Eye infections: None
Other infections: Pneumonia (2 babies)
Abscess of submaxillary gland (1 baby)
None (1 baby)

Various forms of treatment have been put forward from time to time as possible causes of retrolental fibroplasia. Particulars of such treatment are as follows:

Vitamin A: 15,000 i.u. given daily from age of 2 weeks in all cases (water-miscible form never given).
Vitamin E: (Only given in 2 cases after the condition had developed.)
Iron: Given from age of 6 weeks in 3 cases and from 8 weeks in the fourth.
Hormones: None given.
Parenteral blood or plasma: None given.
Exposure of eyes to light: Eyes shaded by thick rubber oxygen mask for five weeks in one case. Other cases treated in Queen Charlotte type of Oxygenaire in rooms with normal lighting.
Penicillin: Given to 3 out of 4 cases for various infections.
Oxygen: Administered for nineteen days, twenty-six days, four weeks, and five weeks respectively.
Feeding: High protein cows' milk, with exception of one case which was given breast milk for the first seventeen days of life.

In all 4 cases the condition was bilateral. In 2 of the babies the fundi were examined at the age of 2 months and appeared to be normal. The condition was discovered at 1 year (1st case), 4 months, 3½ months, and 3 months respectively. In all cases the child appears to be mentally normal. In 1 case a subconjunctival membrane graft was made by Mr. Jameson Evans. In 2 cases large doses of vitamin E were administered and the administration of vitamin A and iron was stopped. One of these babies subsequently developed glaucoma, necessitating the removal of the eye by Mr. Jameson Evans (hæmorrhage was found to be the cause). The second died of pneumonia at the age of 5½ months and the eyes were examined post mortem by Dr. Baar.

In order to facilitate early diagnosis the following policy has been adopted in the Birmingham Premature Baby Units:

The fundi are examined as soon after birth as practicable (in all cases this is done before the age of 4 weeks), and subsequent examinations are made every two weeks, the pupils being dilated for the examination.

Mr. Jameson Evans said that through the kindness of Dr. Mary Crosse he had been able to see 4 of these cases, and he had seen a fifth recently. The case which he would describe was one in which the right eye had a complete retrolental fibroplasia, the left eye an incomplete. It was of some importance and interest from the point of view of the possible development of the condition. It would be seen from his picture (Fig. 1) that there arose from the region of the pars plana a fine ring of tissue which extended immediately behind the lens.

There were no remains of the central hyaloid system. The disc was pale, but, he thought, of normal contour, and there was an enlarged vein passing down in the lower part of the retina. The network showed some finely pigmented cells chiefly in the nasal and lower quadrant. The iris showed no changes suggestive of iritis, but this case had been observed only for three months. The mother, a Pole in a displaced persons' camp, could give little information, and there was no record of the birth-weight, but the child was eight or nine weeks premature.

Drawing by Hamblin

FIG. 1. — Left eye, showing ingrowth of ring of new tissue behind lens: incomplete retrolental fibroplasia.

The clinical features about this case were the shallow anterior chambers, the practically fixed pupils, and the very characteristic appearance of a bowl-shaped grey mass behind the lens in the right eye.

Dr. H. S. Baar showed lantern slides illustrating the histological findings in one of the twins mentioned by Dr. Crosse. There was a detached retina which enclosed a small amount of fibrillary vitreous body. Between detached retina and its pigmented layer there was a highly albuminous exudate with a few shed-off pigmented cells and ghost cells. Only in a few places within the vitreous body were blood vessels present. These were of capillary calibre and not surrounded by connective tissue. Numerous elongated cells posterior to the ciliary body were interpreted as proliferated endothelial cells. Such cells and fibrils of the vitreous were attached to the retina and tags were formed apparently as the result of traction. The ciliary processes were slender and long, but their blood vessels well developed. The clear-cell layer was normal in many places, but proliferation was seen in some and detachment in occasional areas. There were no synechiæ, the iris showed no inflammatory changes and in its vessel layer numerous branched chromatophores were seen.

Mr. P. M. Moffatt, in replying on the discussion, said that if he had omitted to mention corneal opacities, this was in error, but he did know about them. With regard to children born with this condition being members of the same family, in 1939 a mother brought her son aged 2 months to him with what might have been this condition. The child was full term and had weighed 9 lb. at birth. The child subsequently became totally blind and mentally defective, and was at present, aged 10, in a home for mental defectives. Two years later the mother brought her next child—a boy—to have his eyes examined. The eyes appeared to be all right, but two weeks later she brought the child again, saying he was going the same way as the other boy, and that proved to be so. He eventually excised one eye to establish the diagnosis, and the opinion came back "Pseudo-glioma". Three years later the mother gave birth to a child who was perfectly normal, and 2 previous children had been normal. In the children in the Sunshine Homes he saw no case, except those of twins, in which there was a familial connexion.

He had quoted a statement that in America *a* major if not *the* major cause of blindness in infants was retrolental fibroplasia, and that statement he thought he could substantiate. He did not believe it was the same in this country, but he was not prepared to give figures at the moment because of the lack of a proper reporting system. For example, he had heard that evening of several cases to which he had not had access, and unless there was some system of reporting these cases he did not think they could arrive at a figure for the incidence of the condition. How was some co-ordinating machinery for this purpose to be set up? On listening to Dr. Mary Crosse he was agreeably surprised to find that somebody was already doing what he had suggested, and he could not help feeling that in Dr. Crosse's cases the examination of the fundi was probably quite well covered.

Repeated examination need not take place in the very earliest days after birth, but just before the time when it was known that the disease might appear, namely, at the second month, when the membrane might spread across the lens in a matter of a few weeks, then he thought examinations should be made, at any rate at intervals of one week, if that could be done without in any way jeopardizing the viability of the infant.

The President asked whether, once the disease had started, there was any possibility of vitamin E arresting it.

Mr. Moffatt said that there was such a prospect in the early stages. It had been reported that by using a water-miscible preparation of vitamin E and cutting down the intake of vitamin A and iron, the process was arrested and the membrane disappeared.

Dr. Mary Crosse said that that had been tried in 2 of her cases, with no effect.

Mr. Eugene Wolff said that it was obvious from what had been stated that evening that the name "retrolental fibroplasia" was a misnomer. There could be no doubt that they were dealing with a disease entity. He suggested that it be called "Terry's disease". Nobody could quarrel with that, because it was he who put the disease "on the map".

Section of Pædiatrics

President—W. W. PAYNE, M.B., M.R.C.P.

[*October* 28, 1949]

Retrolental Fibroplasia Occurring in Twins.—J. K. MARTIN, M.R.C.P.

D. R. and A. R., male twins, born 17.1.49.

First children of young parents, no consanguinity. No family history of blindness. Born in the 29th week of pregnancy. Birth-weights: (1) A. R., 2 lb. 8 oz.; (2) D. R., 2 lb. 12oz. There was only one placenta and chorion. Lusty at birth and progress favourable. D. R. developed conjunctivitis at 2 weeks and had a course of penicillin eye drops. Both became rather anæmic. Hb: 52% A. R., 66% D. R. Treated with iron. Discharged from hospital at 8 weeks, A. R. 5 lb. and D. R. 5 lb. 7 oz.

Mother perfectly well throughout pregnancy.

A. R. admitted to hospital on 20.7.49, for operation for strangulated right inguinal hernia. Parents had not noticed anything wrong with the children up to this time. It was noticed that both children had a roving nystagmus and microphthalmos. No attempt to follow a light or take objects. They were aware of a bright light and the pupils reacted sluggishly. The red retinal reflex was absent. Mr. P. McG. Moffatt reported "Retrolental fibroplasia. Deficient differentiation of anterior layers of the iris. Adhesions from anterior surface of the iris to the lens capsule".

Both children are otherwise healthy and developing normally.

Investigations.—(1) *W.R. and Kahn:* mother negative on 9.9.48.

(2) *Blood Groups:*

(*See also* p. 226, Fig. 1.)

Retrolental Fibroplasia in a Premature Baby.—A. WHITE FRANKLIN, M.B., F.R.C.P.

S. B., a first-born female, was born 3.1.49, at the 28th week. The mother had had a normal pregnancy with routine vitamins irregularly taken, and was admitted to Paddington Hospital with a threatened abortion two weeks after a fall on the abdomen.

Delivery was spontaneous, the mother being given sodium amytal 3 grains and pethidine 150 mg. The baby weighed 3 lb., measured 14½ inches with a skull circumference of 11 inches.

At first feeding was difficult, but after a period of tube feeding during the first week, progress was steady on expressed breast milk, and later on Humanized Trufood. Vitamin B (3 mg.), vitamin C (5 mg.) and adexolin (from 2–20 minims) were given daily. Much of the first month was spent in an oxygen tent. The baby left hospital aged 56 days, weighing 5 lb. 8 oz.

The mother suspected blindness at this time and at three months attended Moorfields Hospital where Mr. A. G. Leigh diagnosed blindness due to retrolental fibroplasia. He reported: "Very shallow anterior chambers, both eyes showing well-marked posterior synechiæ with atrophic irides. Both lenses were clear and a dense white fibrous membrane was seen in the vitreous immediately behind the lens in each eye." The right lens was needled without benefit.

Progress was at first steady but slow, and at 9 months she weighed only 11 lb. 13 oz. She then began to refuse feeds, to vomit, and to lose weight. At the age of 38 weeks (28.9.49) she was admitted to Saint Bartholomew's Hospital for feeding regulation. She weighs 11 lb. and appears thin, small and blind. She cannot hold her head steady nor sit up. The eyes appear sunken and small. Skull circumference is

16½ inches. X-ray of the skull is normal and shows orbits of normal size. Beyond the eye condition, which is as described above, examination reveals only a small hæmangioma in the right pubic region and pallor of mucous membranes (R.B.C. 5,000,000 per c.mm.; Hb 6·6 gramme per 100 c.cm. (48%); C.I. 0·49). Blood Wassermann negative.

This is a case of bilateral retrolental fibroplasia in a premature small baby, complicated by general failure to thrive, anæmia, feeding difficulty and marked delay in behaviour development. No unusual drug or vitamin treatment was given to either the mother or the baby. The baby, like so many small premature babies, spent much of the first weeks of life in an oxygen tent.

Examples of this condition have been recorded in England during the last seventy years (Nettleship, 1873). The late Dr. Terry of Boston (1942) first drew the attention of pædiatricians to the association with prematurity. Although relatively common in Boston this is still a rare disease in and around London.

? **Periarteritis Nodosa.**—P. M. M. PRITCHARD, M.B.

Girl aged 4 years 8 months. Well until May 1948, when she developed puffiness of the eyelids which lasted two months. She was anorexic and miserable.

In July 1948 she had acute tonsillitis, treated with sulphamezathine. In the next eight weeks, she had recurrent evening pyrexia up to 101° F., night sweats, and a loss in weight of 5 lb.

Nothing relevant in the past or family history. Had never had a sulphonamide before.

She was admitted to hospital on September 24, 1948. Age 3½ years. Weight 27 lb. Tonsils septic. Widespread rash consisting of small flat-topped polygonal papules, surmounted by a minute vesicle. It became more prominent in the two days following tonsillectomy on October 6, 1948; lasted about eight months, then faded gradually leaving small, puckered scars.

Skin biopsy on November 30, 1948, showed "a granulomatous lesion in the superficial corium. Localized fibrinoid degeneration of collagen, aggregation of mononuclear cells mainly lymphocytes, epithelioid cells and fibroblasts, as well as a few foreign body giant cells. Œdema of precapillary vessels".

January 1, 1949: Transient pain in legs and flanks.

In February 1949 the liver began to enlarge, until it was 3 cm. below the right costal margin. The spleen became palpable a month later.

March 26, 1949: Bilateral basal pneumonia, after which she had albuminuria for three weeks. Urinary deposit normal.

During April 1949 there was gradual cardiac enlargement, with bilateral pleural effusions and congestion of the lung fields, followed in May 1949 by congestive cardiac failure. The electrocardiogram on May 30, 1949, showed a P–R interval of 0·28 sec. The cardiac failure improved with digitalis.

Irregular fever up to 101·5° F. during June and July 1949.

She returned to hospital on August 28, 1949, after two months' convalescence and was found to have a blood pressure of 165/120. Cardiac enlargement and hepatosplenomegaly were still present. No nodules. Good peripheral pulses. Tachycardia 110 to 130.

The hypertension has continued, unaffected by sedation. Albuminuria has been present for the past two months, with a slight increase in the red cells, white cells and casts.

B.S.R. persistently raised (28–48 mm.) throughout the illness, which has been almost afebrile. Moderate orthochromic anæmia (8·8 to 10·6 grammes Hb/100 ml.). White blood count between 7,400 and 14,600 per c.mm., with a normal differential count, and no eosinophilia. Antistreptolysin titre less than 20 units/ml. on

May 19, 1949. Renal function and intravenous pyelogram normal. Occult blood negative. W.R. and Kahn negative. Mantoux 1 : 100 negative on three occasions. Liver function tests within normal limits.

Muscle biopsy on October 8, 1949, showed "numerous granulomatous lesions in relation to small arterioles, consisting of macrophages, lymphocytes and young fibroblasts. There is necrosis in the centre of some lesions, but no caseation. In a few nodules giant cells of the Langhans type are present. The arterioles near the nodules show prominent endothelial lining cells, but no evidence of necrosis in their walls, only slight mononuclear cell infiltration.

The smaller nodules are highly reminiscent of Aschoff bodies (Figs. 1 and 2).

FIG. 1. × 95

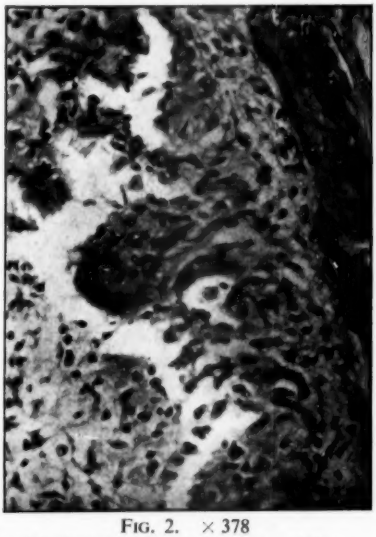

FIG. 2. × 378

Muscle Biopsy.—Showing granulomatous lesion with giant cells in relation to arteriole.

Comment.—Periarteritis nodosa, running a subacute course and affecting mainly the small arteries, would account for the rash, hepatosplenomegaly, myocarditis and hypertension.

As yet, no definite histological diagnosis can be made, though the lesions show some resemblance to the granulomata of periarteritis nodosa described in the lungs by Sweeney and Baggenstoss (1949); to the granulomatous arteriolitis of Teilum (1946), and to some of the heterogenous group described as non-specific focal myocarditis by Marcuse (1947). However, in the sections examined, no necrosis of the arterial wall has been seen.

It seems most probable that this case is one of the group of pathogenetically-related collagen-vascular diseases, with points in common with periarteritis nodosa and acute rheumatism, but, clinically and histologically, typical of neither.

Persistent Left Cardinal Vein.—J. DEAN, M.R.C.P. (for I. M. ANDERSON, M.D.).

G. B., male, aged 7 years.

First seen September 1948.

History.—Breathless since birth but improving on the whole. Blue attacks recently.

On examination.—Slight build. Slight cyanosis. Left side of chest more prominent than right. Diffuse apex beat in fifth left space, ¼ in. outside midclavicular line. Loud first sound at apex. Apical second sound duplicated. Faint second sound at aortic area. Harsh systolic murmur at apex and in third and fourth left interspaces near sternum. Faint early diastolic murmur internal to apex. B.P. (arm) 95/65.

X-ray of chest: There is a persistent left cardinal vein with enlargement of the right ventricle.

Angiocardiogram: Interatrial septal defect with a right-to-left shunt and probably a number of abnormal arteries coming off the aorta.

E.C.G.: Right ventricular preponderance.

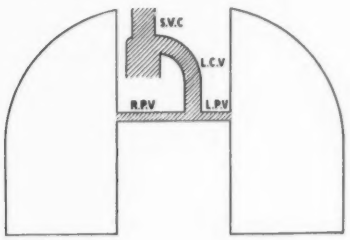

FIG. 1.—Probable arrangement of pulmonary venous system in case of persistent left cardinal vein. S.V.C. = superior vena cava. L.C.V. = left cardinal vein. R.P.V. and L.P.V. = pulmonary veins.

Multiple Cardiac Anomalies with Dextrocardia and Situs Inversus.—J. DEAN, M.R.C.P. (for I. M. ANDERSON, M.D.).

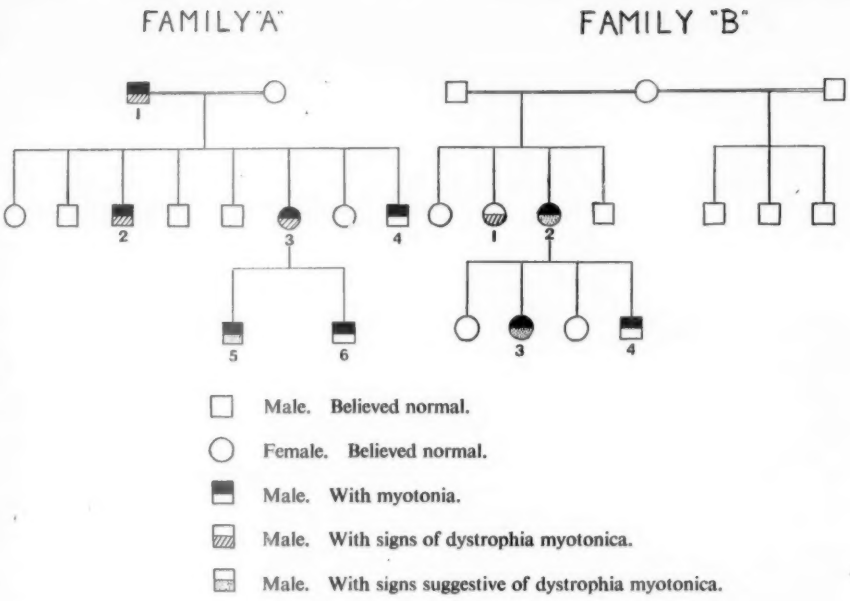
L. P., female, aged 20 months.

First seen July 1949 with blueness on exertion for ten months and severe cyanotic attacks.

On examination.—Thin, flabby child. Slight cyanosis at rest, marked cyanosis on exertion. Apex beat not definable. Heart sounds best heard in fourth left space near nipple. Harsh systolic murmur maximal at left border of sternum but audible all over heart.

X-ray of chest: "Cardiac apex is on right side. . . ."

X-ray of abdomen: Stomach is on right side.



Angiocardiogram: "The superior vena cava lies on the right side. The contrast medium passes into both auricles simultaneously. The aorta fills as soon as the 'right' ventricle, but both ventricles fill almost simultaneously. The pulmonary artery arises from the 'left' ventricle which lies on the right side, but shows no evidence of stenosis" (Dr. J. H. Smitham).

Two Families with Myotonia.—D. A. J. WILLIAMSON, M.D., M.R.C.P. (for W. G. WYLLIE, M.D., F.R.C.P.).

FAMILY A

James T. (5) aged 10 years. Stiffness noticed since infancy, walking always difficult, particularly after sitting or standing still. Runs stiffly until he has become "loosened up". Hands and arms also stiff at times. The condition is worse when he is excited.

On examination.—Normal intelligence and appearance except for slightly excessive muscular development for age. No myopathic facies. Eyes normal. No cataracts seen. Genitalia normal. Slight but definite sluggishness in relaxing grip. Gait stiff at first but soon becomes normal. Tendon reflexes normal. Mechanical myotonia obtainable in most muscle groups, e.g. tongue, thenar eminences and calf. Minimal wasting of both thenar eminences with abnormal abduction of thumbs. E.C.G. normal.

Alan T. (6) aged 4 years. Stiffness of legs noticed at age of 2 years, which has become more marked. Symptoms resemble those of brother (*vide supra*).

On examination.—Normal facies. Normal build. Eyes normal. Gait stiff at first. Mechanical myotonia in usual muscle groups. No wasting. Tendon reflexes brisk. E.C.G. normal.

Family history.—Maternal grandfat er (1) had myotonia and cataract.

Maternal uncle (2), aged 49 years, has myotonia with slight muscle wasting.

Another maternal uncle (4), aged 37 years, has myotonia.

Both are living normal active lives.

Mother (3), aged 42 years, has had myotonia since childhood and now has slight wasting of thenar muscles with abnormal abduction of thumbs. Otherwise well (*see* Family Tree A).

FAMILY B

Jean D. (3) aged 16 years. Stiffness noticed at age of 1 year when it was observed that she would fall if placed on her feet but could stand if left to herself. Has always had difficulty with walking, particularly on gradients and stairs. Stiffness wears off after short period of exercise. Condition seems better in damp weather but is not affected by temperature. Worse if excited or harassed. She is now working without disability as a bookbinder.

On examination.—Rather thin-faced girl. Normal intelligence. Eyes normal. Slight wasting of thenar eminences. Definite sluggishness in relaxing muscles, e.g. grip or straightening knee. Mechanical myotonia obtainable in tongue, calf, thenar eminences, etc. E.C.G. normal.

William D. (4) aged 12 years. Symptoms not noticed until the age of 5 years : now closely resemble those of sister (*vide supra*) except that recently he has had attacks of severe cramp-like pain in the abdomen. These mostly occur at night and are relieved by warmth. Condition less severe in warm weather. He was treated with quinine hydrochloride 5 grains b.d. for several months with apparent improvement but treatment was suspended owing to toxic symptoms.

On examination.—Normal intelligence and appearance. Muscular development probably rather excessive. Eyes normal. No muscle wasting. Mechanical

myotonia obtainable at usual sites. Definite sluggishness in relaxing muscles. E.C.G. normal.

Family history.—Mother (2) has myopathic facies with receding hair and mechanical myotonia in tongue and calf. She has failing vision in the left eye, ? cause.

A maternal aunt (1) died aged 11 years suffering from mental deficiency and cataract.

Another maternal aunt has poor vision which has not been investigated (*see* Family Tree B).

Discussion

In both of these families the condition was undiagnosed for many years with the result that the unfortunate sufferers had usually been dubbed either lazy or naughty, especially since the myotonia is aggravated if the patients are harassed.

Nomenclature.—In the classical accounts of myotonia three separate conditions are described:

(*a*) Myotonia congenita or Thomsen's disease is a familial complaint often appearing in early childhood in which myotonia with muscular pseudo-hypertrophy is the only symptom.

(*b*) Dystrophia myotonica is also a familial complaint but it does not usually appear until adolescence, although cases as young as 2 and 3 years have been described. The myotonia is usually less marked and is uncommon in the lower limbs. It is accompanied by muscle wasting particularly of the facial, sterno-mastoid, forearm and thenar muscles. There are also a number of very important associated conditions. These include: Cataract; fronto-parietal baldness; cardiac changes (P-R interval prolonged); genital atrophy; mental and social deterioration.

(*c*) Paramyotonia is a condition in which myotonia occurs only in cold weather.

According to some authorities, notably Maas and Paterson (1939), however, these three conditions are all part of one disease. They state that cases of myotonia congenita if examined carefully and followed up adequately can always be shown to possess some of the characteristic features of dystrophia myotonica. On the other hand Thomasen (1948) in a review of myotonia in Denmark found five families comprising 29 myotonics whom he considered showed no evidence of dystrophia myotonica.

Our cases would seem to support Maas and Paterson. Superficially they would appear to be suffering from myotonia congenita and the age of onset would tend to confirm this diagnosis. However, two of the children show slight wasting of the thenar muscles while in both families there is evidence which is very suggestive of dystrophia myotonica.

The matter is of importance as regards prognosis. It is usually stated that dystrophia myotonica carries a grave prognosis and in Denmark it is recommended that sufferers from this complaint should be sterilized. However, if it is accepted that Family A above are, in fact, suffering from dystrophia myotonica it will be seen that the prognosis is not necessarily as grave as is sometimes supposed.

Idiopathic Pulmonary Hæmosiderosis.—L. G. Scott, M.R.C.P. (for P. R. Evans, M.D., F.R.C.P.).

A. W., male, aged 9 years. Parents not cousins. Only child. Not been abroad. 20.9.49: Admitted to hospital because of his pallor.

Family history.—Mother died May 1949 from "multiple cerebral tumours". Father has lived abroad many years, had amœbic dysentery, bilharzia and malaria, but well now except for occasional attacks of malaria.

Past illnesses.—Aged 2 years: whooping cough. Aged 7 years: Intermittent bouts of diarrhœa for about six months. Watery yellow stools without blood or mucus. Attacks seemed to be precipitated by excitement. (No attacks for past two years.) A blood-count at the time was said to have shown a slight anæmia.

Personal history.—Appears to have developed normally; intelligent boy.

Present illness.—Always pale. Early this year became more than usually pale and developed a non-productive cough and some pyrexia. No acute dyspnœa or cyanosis. X-ray on 4.2.49 showed mottled opacities at both bases and the left mid-zone (Fig. 1). (Sanatorium treatment suggested.) After six weeks made a seemingly good recovery and was sent to boarding school in Sussex.

FIG. 1. 4.2.49

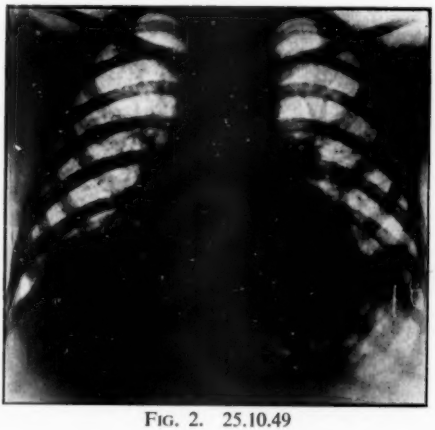

FIG. 2. 25.10.49

Middle of August 1949 began to get breathless on exertion. On return to school in first week of September noticed to be unduly pale. No cough. No bleeding. Put to bed and had slight pyrexia which subsided after a few days. Blood examination showed considerable anæmia, and X-ray on 20.9.49 showed a fine reticulation at both bases. Admitted to Guy's Hospital on 20.9.49.

On examination.—Well-nourished, pale, ginger-haired boy, with freckles. Medium-pitched systolic murmur heard all over præcordium, persistent in all phases of respiration and with change of posture. Pulse 90 regular. B.P. 110/70. Tip of spleen palpable. Liver 1½ f.b. below costal margin. Other systems N.A.D.

Chest X-rays.—4.10.49: Fine reticulation at both bases. 21.10.49: Mottled opacities appearing at the bases. 25.10.49: Marked increase in basal opacities (Fig. 2). 28.10.49: Rapid improvement. Mantoux 1 : 1,000 negative; 1 : 100 positive. Blood-count: Hb 52%; R.B.C. 3,200,000 per c.mm. C.I. 0·8. Marked anisocytosis and irregular anisochromia; moderate poikilocytosis. No nucleated red cells. Reticulocytes 8%. W.B.C. 4,700 per c.mm. (P. 40%, L. 50%, E. 6%, M. 3%, B. 1%). Polymorphs show no right or left shift. Lymphocytes mainly small type. Platelets 280,000 per c.mm., morphologically normal. Sternal puncture: Marrow shows granulocytic left shift with eosinophilia. Bleeding time normal. Clotting time at 37° C., 2 min. (normal 1¼ to 1¾ min.). Twenty-four hour urine quantitative urobilinogen estimation—less than 1 mg. (vol. 455 ml.), a low normal value. Van den Bergh, direct, negative. Serum bilirubin 0·2 mg. per 100 ml. Serum non-hæmin iron: 55 mg. Fe per 100 ml. serum (a low figure). Red-cell fragility: Hæmolysis: commenced 0·44% saline, complete 0·3% saline. Occult blood in stool: two specimens showed weakly positive guaiac and benzidine reactions. Donath-Landsteiner test for hæmolysins negative. W.R. and Kahn negative.

Urine: No iron detected. Arm-tongue circulation time 8 sec. Stool: No ova or parasites. C.S.F. normal. E.E.G.: Suggests epilepsy. No sputum could be obtained.

Progress.—24.10.49: Developed pain below right costal margin. Temperature rose to 103·8°. Not acutely distressed and no cough. No cause found for pyrexia except lung changes. Diminished movement and impaired percussion note at the right base and fine crepitations at both bases on 25.10.49 (X-ray Fig. 2). Given penicillin. Had a generalized epileptic fit on 25.10.49. No abnormal neurological signs. 29.10.49: Had a further bout of pyrexia associated with headache and stiffness of the neck. Rapid recovery from this. Received iron therapy from 11.10.49. Blood-count on 26.10.49 showed little change.

Cortical Hyperostosis.—J. SAKULA, M.D., M.R.C.P., D.C.H.

Thomas W., born 2.1.49. Normal birth and neonatal period. Birth-weight 8 lb. 4 oz. Mother W.R. negative and Rhesus negative. Child Rhesus positive. Fed on National dried milk.

Admitted to Central Middlesex Hospital, aged 3½ months, as a possible case of syphilitic osteitis of the right forearm, with pain, swelling and lack of movement for about one week.

On admission.—Well-developed child. Weight 12 lb. Right forearm swollen and tender with pseudoparalysis. Head looked large because of swollen lower jaw (Fig. 2, *see* opposite for figures) and he also had palpable thickening of both clavicles. There was no enlargement of lymphatic glands and spleen not palpable.

X-rays showed widespread involvement of skeleton, the distribution and character of the lesions being typical of Caffey's original description (*see* Fig. 1 and radiographs A – E, Fig. 3).

Other investigations.—Blood W.R. negative. Patch test negative. Blood-count—Hb 55%; W.B.C. 27,800 (49% neutrophils). B.S.R. 44 mm in one hour. Serum calcium 9·3 mg., inorganic phosphate 3·4 mg., alkaline phosphatase 38·4 units, per 100 ml. Antistreptolysin titre 10 units per ml. Biopsy not done.

Progress.—He was pyrexial for over six weeks. His marked anæmia gradually improved, but there was a persistent leucocytosis. The B.S.R. returned slowly to normal.

The affected bones showed: (*a*) Tender swelling of the deeper overlying soft tissue. (*b*) X-ray signs increased at first, then subsided over a period of four to six months. (*c*) Some swelling and tenderness persisted over the affected bones.

There were no constitutional symptoms throughout the course of the disease and the weight increased steadily.

No special treatment was given.

Pyonephrosis in "Third" Kidney with Ureter Opening into Urethra.—A. C. WILSON, O.B.E., M.B., Ch.B. (for J. C. YATES BELL, F.R.C.S.).

J. S., first seen aged 1 year 7 months. Twin girl; 8 months' pregnancy; normal labour; birth-weight 4 lb. 10 oz. Breast-fed 3/52 then Nestlé's Milk.

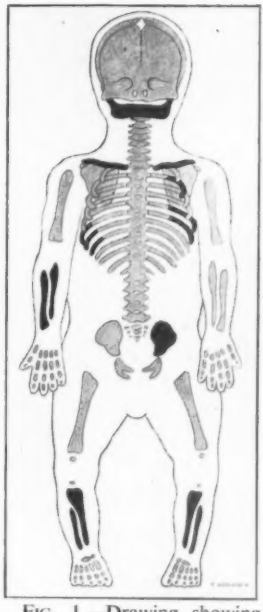
Admitted Fever Hospital with gastro-enteritis, aged 3 months. Transferred from there to Queen Mary's Hospital for Children, Carshalton, 30.4.48 as ? developmental defect, at 15 months of age.

Presenting symptoms and signs.—Anæmia, marked anorexia, vomiting, constipation, failure to thrive; weight aged 15 months, 9 lb. 14 oz.

On examination.—Small, thin, pale, weak child; large distended abdomen; masses in L.I.F. extending across lower abdomen; two small masses in R.I.F. ? fæcal.

Progress and investigation.—Unsatisfactory. 1 lb. gain in weight in three months. Marked anorexia, vomiting once to thrice daily, sometimes projectile. Abdominal distension a sustained feature with masses nearly always palpable before washouts.

(*continued on* p. 244).



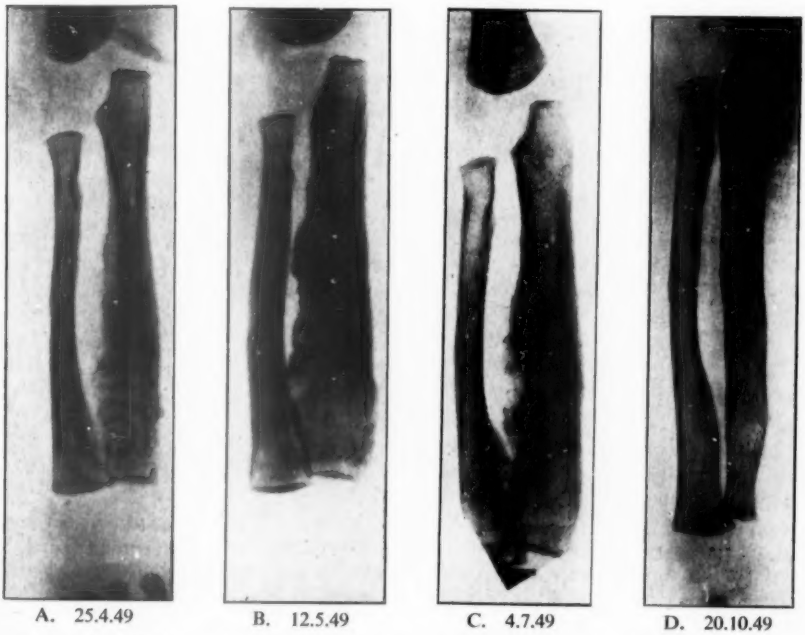


FIG. 1.—Drawing showing the skeletal distribution of the lesions.

FIG. 2.—Photograph of the child showing the enlarged jaw.

FIG. 3E. 31.5.49

A. 25.4.49 B. 12.5.49 C. 4.7.49 D. 20.10.49

FIG. 3.—X-rays demonstrating: (*a*) The character of the lesion and the process of healing in the right forearm (Films A, B, C and D). (*b*) The layered periosteal reaction as shown in the fibula (E).

Cortical Hyperostosis.—Dr. Sakula.

(*continued from* p. 242)

Constipation relieved only by enemata, washouts, &c. Symptoms became suggestive of megacolon but no response to prostigmine. Washouts results became increasingly bulky. Continued anæmia, even following blood transfusions.

Hb averaged 47–54%. White cells averaged 7,000–10,000; normal proportions for age. Blood urea 35 mg. %. Repeated specimens of urine N.A.D. Fæcal fat prior to admission 47·7 grammes %, increasing to 62·2%. Barium enema, at 16 months of age—nothing definite (Fig. 1). At 18 months of age a swelling became

FIG. 1.—Barium enema at 16 months. Abdominal distension, otherwise nothing of note.

FIG. 2.—19 months—sinus pyelogram shows dilated upper half of the right kidney with dilated ureter to bladder and a small sinus (? prolongation of ureter) to the urethra. Abdominal distension.

FIG. 3.—19 months—Left retrograde pyelogram normal. Abdominal distension.

palpable also above R.I.F. Barium meal at 18 months of age (postponed due to intercurrent chest infections) showed gut displaced to left. Average T.P.R. 97·8°, 126, 36.

At 18 months (Mr. Yates Bell): Mass in abdomen diagnosed as probably a large right renal swelling ? hydronephrosis.

Cystoscopy: Normal bladder and ureteric orifices. Right ureter catheterized at 10 cm.; good dye excretion from right ureteric catheter. No pus in bladder. Gush of pus from urethra on pressure over abdominal wall, and examining finger in rectum, i.e. *Diagnosis*: Pyonephrosis in "third" kidney with ureter opening into urethra.

First operation.—Nephrotomy. Right lumbar incision; large kidney (normal exterior) incised; purulent, stinking urine evacuated; heavy mixed growth of staphylococci, coliform bacilli and pneumococci. Tube inserted for three months.

Sinus pyelogram showed dilated upper half of the right kidney with dilated ureter to bladder and a small sinus (? prolongation of ureter) to the urethra (Fig. 2). Left retrograde pyelogram normal (Fig. 3).

At 21 months: *Second operation.*—Right nephrectomy (Mr. Yates Bell); hemi-nephrectomy was found impracticable.

On section ureteric mass contained two ureters, one dilated and passing to upper pole, one normal size with small area of normal tissue in lower pole.

Gained 5 lb. in weight in the three months following nephrectomy, and fæcal fat, which had been 62 grammes % before operation, fell to 19 grammes.

Child discharged home plump and well. Hb 60% but steadily increased to normal; now 80%. Stature of child still small but improving.

Present condition (*aged 2 years 9 months*).—Weight 23 lb. 3 oz. Height 27½ in. Fæcal fat 22 grammes %.

Comment.—Case of special interest because of long medical history with normal white cell count, apyrexia, absence of abnormal urinary signs and rapid recovery following nephrectomy. A discharge apparently from the vagina had very occasionally been found on insertion of the rectal tube for washouts. This discharge contained the same organisms as were found in the kidney.

Repeated respiratory infection due to debility of child and abdominal distension ceased following operation.

Mr. Yates Bell commented on the importance of ascertaining before operation that the left kidney was normal, and ensuring that it was not linked with the abnormal right kidney. The child's twin had died at the age of 3 months from gastro-enteritis. Unfortunately there was no post-mortem.

? **Sarcoidosis.**—E. HINDEN, M.D., M.R.C.P.

John M., born 14.1.48.

Was admitted to Whipps Cross Hospital on April 3, 1949. He had been ill for five days with fever, malaise and vomiting. Examination showed an acute pulmonary infection, which at first was thought to be a bronchopneumonia. Temperature subsided in twenty-four hours with sulphamerazine but the signs in his chest persisted. On 21.4.49 he contracted measles—a ward infection—from which he made a good recovery. Following this he became lively and active, and gained weight, from 18 lb. on admission to 21½ lb. on discharge on June 29. Yet the moist crackles persisted throughout.

X-ray taken in April showed the "snow-storm" usually identified as miliary tuberculosis, and this appearance has persisted unchanged till October, by which time he has gained another 5 lb.

Mantoux tests, 1 : 1,000 and 1 : 100, both negative. No family history of tuberculosis. Chronic miliary tuberculosis seems unlikely in the face of his obvious well-being and rapid growth (8 lb. in six months, in the second year of life) and the negative Mantoux tests. Sarcoidosis seems a possibility, but there have been no other manifestations, and I have been unable to find any reference to this disease in so young a child.

Chorea following Temporary Anoxia.—R. C. MAC KEITH, D.M.

[*November* 25, 1949]

Lupus Vulgaris and Primary Intrathoracic Tuberculosis.—F. S. W. BRIMBLECOMBE, M.D., M.R.C.P. (for REGINALD LIGHTWOOD, M.D., F.R.C.P.).

Boy, aged 2 years and 3 months.

Present illness.—In January 1949 developed a small red spot on his left cheek. This has grown gradually larger and has peeled on three occasions. No other symptoms ; has gained weight steadily.

Past history.—Drank unboiled milk until April 1949. In contact with tuberculous friend of family from January 1948 until March 1949.

Examination (28.10.49).—Nutrition good. Papular erythematous lesion on left cheek ½ in. in diameter showing "apple jelly" nodules. No cervical adenitis.

Lungs: Impaired percussion left upper zone posteriorly with diminution of breath sounds.

November 1949: Tuberculin jelly test strongly positive. X-ray of chest: "Considerable left hilar adenitis". E.S.R. 2 mm. in one hour. Gastric lavage (three times): No acid-fast bacilli on film or on culture.

Comment.—The association of lupus vulgaris with primary intrathoracic tuberculosis is unusual, though probably not so uncommon as the literature suggests.

The treatment of lupus vulgaris with high dosage of calciferol is now established. If given in other tuberculous conditions such as glandular or joint lesions, there is some evidence (Macrae) that high dosage of calciferol may cause an initial flare-up of the lesion, although subsequent healing appears to be accelerated.

Until further information is available, however, it would seem inadvisable to treat intrathoracic tuberculosis with such high doses of calciferol as are required in lupus vulgaris in view of the risks arising from the possibility of the initial flare-up. Further trials of high dosage calciferol in primary intrathoracic lesions perhaps with streptomycin and para-aminosalicylic acid may show such caution to be unnecessary.

MACRAE, D. E. (1946) *Lancet* (ii), 529.

Mitral Stenosis First Discovered at the Age of 2½ Years.—GORDON HESLING, M.B., M.R.C.P., D.C.H. (for J. P. M. TIZARD, B.M., M.R.C.P., D.C.H.).

Michael M., aged 3 years, is the fifth of six children. The remaining members of the family are well and no member has had rheumatic fever. The family is in poor circumstances.

He had gastro-enteritis at 1 year and bronchitis at 2 years. He was given no vitamin-D supplements.

Admitted to hospital on 27.6.49 with a history of cough and feverishness for ten weeks. He was found to have a collapse in the right middle lobe and in the lingula. He had evidence of mild rickets. The cardiac murmur was noted on admission. The collapse re-expanded, the only unusual feature being a tachycardia (90 to 130) persisting throughout his stay in hospital, which was until 26.9.49. There was no other evidence of active rheumatism and his E.S.R. was never above 15 mm. in one hour.

The heart showed no clinical enlargment (apex beat 2½ in. from mid-line in the fifth space). Over a small area about the apex were heard a crescendo presystolic murmur continuing into the first sound, a second sound and a third sound followed by a diminuendo mid-diastolic murmur. The second sound was accentuated at the pulmonary area and was reduplicated.

The heart on screening showed an enlarged left auricle but no other abnormality. (*See* Figs. 1 and 2.)

The E.C.G. showed Q2 and Q3 to be present but was reported as physiological.

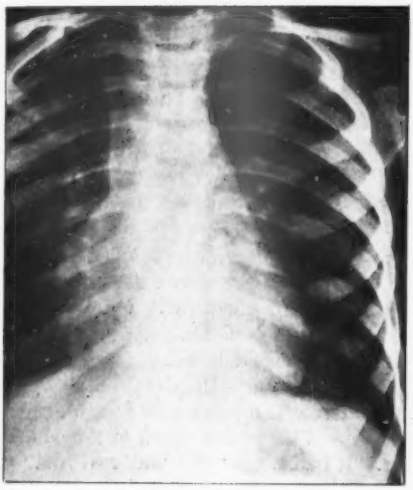

FIG. 1.—Chest, A. P. view, showing normal heart outline.

FIG. 2.—Chest, right oblique, showing indentation of œsophagus by enlarged left auricle.

Three similar cases have been found in the literature (aged at death 1 year 8 months, 2 years and 2 years 8 months), in all of which post-mortem revealed the same changes as are found in chronic rheumatic valvulitis in the adult.

In all of these cases enlargement of the left auricle was found, whereas in cases of congenital mitral stenosis of developmental origin there has been either hypoplasia of the whole of the left side of the heart (including the left auricle) or complex deformities including interventricular septal defect and patent ductus arteriosus of which, in this case, there is no evidence.

Congenital Dermal Sinus (Connexion with Intradural Dermoid Cyst Leading to Spinal Meningitis).—J. P. M. TIZARD, M.R.C.P., D.C.H.

Diane B., born October 24, 1946.

A small punctum at the upper part of the sacrum was noticed when the child was a few weeks old. This first discharged a little caseous material on February 12, 1949, one week after a fall. The sinus had closed by February 23, 1949, but she then became ill with fever, vomiting, stiff back and later pain in the toes. From March 3 to 5, 1949, she was given sulphonamide.

On March 7 she was admitted to hospital with signs of meningitis and treatment with penicillin and sulphamerazine was begun. Lumbar puncture was repeatedly unsuccessful, but on March 10, 1949, cisternal puncture revealed a turbid yellowish fluid containing 640 white cells per c.mm. and 610 mg. of protein per 100 c.c. For the next two weeks intrathecal penicillin and fibrinolysin were administered daily by the cisternal route and the cells and protein dropped towards normal with slight clinical improvement. Culture of the C.S.F. was repeatedly sterile. On March 25, 1949, she developed measles. On March 29 the C.S.F. white cells were again raised and intrathecal penicillin treatment was recommenced. On April 2 the sinus reopened and discharged a little pus; two days later there was acute retention of urine and on the following day a flaccid paralysis of both legs. X-rays of the spine had shown no evidence of osteomyelitis but a possible spina bifida occulta of S.2.

She was then transferred to the Atkinson Morley Hospital Neurological Unit where myelography showed a complete block at the level D.4–5.

1*st Operation.*—April 14, 1949 (Mr. Valentine Logue): Laminectomy D.4, 5 and 6. Cord completely surrounded by thick yellow adherent pus. This appeared to extend cranially and caudally. It was quite impossible to introduce a catheter in either direction. The pus was removed in some areas to expose the cord which was rather thin and pale in colour with blood-vessels very shrunken.

Post-operatively there was incontinence of fæces and urine, but otherwise no change.

2*nd Operation.*—May 23, 1949 (Mr. Valentine Logue): Laminectomy L.3–S.1. Incision from spine L.2 to S.3, a portion of skin being left round the cutaneous sinus. From the skin opening a tubular sinus 2 mm. in diameter led down to a defect 1 cm. across in the second sacral laminæ. At this level the track opened up into a sac 2 × 1 cm. which was full of fluid pus and cheesy dermoid contents. The sac then narrowed to a diameter of 2 mm. to enter the dura. The dural neck of the sac was encircled and the incision extended upwards. The nerve roots were firmly bound together in hard organizing pus. The dermoid lay in the centre of the cauda equina and measured a centimetre in diameter. It had a very thin wall and had to be removed in sections. Everywhere the cauda equina was matted in a solid organizing mass.

Microscopic examination of the intradural mass confirmed that it was a dermoid cyst. Culture of the contents was sterile.

About three weeks later there was some return of power in the proximal limb muscles. She regained control of defæcation and micturition about two months after the operation. She has been home since July 29, 1949, and although there is some spastic paresis and wasting of the right leg, she can walk well.

Comment.—32 cases of congenital dermal sinus communicating with the spinal dura have been reported [1–24]. In 13 cases the sinus was connected with intraspinal dermoid cysts and in 1 case with a "teratoid" tumour [17]. 2 cases of similar sinuses communicating with subdural dermoids within the skull have also been reported [24].

There seems to be no pathological distinction between these rare dermoid sinuses and the common pilonidal sinus except for the dural connexion and this may simply be related to their localization.

In only one [8] of these 32 cases was the sinus found in the sacrococcygeal area, where the common pilonidal sinus is almost invariably found; the remaining 31 were found at all levels from the cervical spine down to the second sacral vertebra where the subdural cavity ends.

In a review [25] of 400 cases of pilonidal sinus Rogers and Dwight found no communication with the dura, but in every reported case of congenital dermal sinus above the sacral level such a connexion has existed [19].

Dermal sinuses are thought to result either from an incomplete closure of the primitive neural canal [26] or from a failure of separation of the neural crest ectoderm from the cutaneous epithelial ectoderm at the site of the deformity [7].

The theories are not mutually exclusive; the latter probably accounts for the majority of cases in which the sinus extends to the spinal meninges, without involving the cord.

However, the former must be invoked where the sinus is shown to communicate with the central canal of the cord as in one case where such a communication took place through a patent filum terminale [14].

The finding of a subdural teratoma in connexion with a congenital dermal sinus suggests yet a third alternative ætiology.

The prognosis following radical removal of the sinus (and, where present, the dermoid) is often surprisingly good even where considerable cord damage has taken

place. The aim, however, should be to eradicate any sinus above the sacrococcygeal area as soon as possible after its detection, before repeated infections have taken place.

(I wish to thank Mr. Wylie McKissock for permission to report the findings at the Atkinson Morley Hospital and Mr. Valentine Logue for his operation case notes.)

Acute Aleukæmic Lymphatic Leukæmia Treated with Aminopterin and Blood Transfusions.—C. P. Alexander, M.B. (for Zina E. Moncrieff, M.R.C.P., D.C.H.).

D. M., female, born 26.10.45.

June 1949, feverish cold with loss of appetite. One week later, tired, pale, and showing signs of bruising easily. Severe anorexia. Admitted to hospital at Brighton.

Hb 66%; W.B.C. 8,450 per c.mm. (P. 1, L. 96, M.3%). Anæmia became worse; transfusion 350 c.c. Group O blood.

Admitted Royal Free Hospital 28.7.49: Very ill. T. 104°. Petechiæ on trunk, arms, legs and back. Subcutaneous nodules, red and raised on both legs. Bleeding from gums; tonsils infected (hæmolytic streptococci, Group A). Palpable lymph glands in cervical region, right axilla and both groins. Liver and spleen enlarged.

Hb 40%; R.B.C. 1,820,000 per c.mm.; W.B.C. 750 (polys. 5%, lymphos. 90%, 5% immature forms). Platelets 50,000. Bleeding time over half an hour.

Sternal puncture: Moderately cellular marrow, typical of acute lymphatic leukæmia. 80% of cells were of lymphocyte series, majority immature para-forms. Myeloid series absent earlier. Erythropoiesis depressed, normoblastic in type.

X-ray long bones: Typical leukæmic rarefaction at diaphyseal ends.

Urine normal.

Treatment.—Transfused with 300 c.c. Group O, Rhesus-positive blood on 28.7.49 and 5.8.49. Penicillin 1 mega unit daily in four doses from 28.7.49 to 6.8.49. Temperature normal on 4.8.49. Aminopterin 1 mg. daily in one dose for fifteen days when it was discontinued owing to toxic manifestations: (Anorexia, vomiting, severe epistaxes). Ferri et ammon. cit. grains 20 b.d. Vit. B, C and D.

Progress.—Improved after two weeks. Petechiæ, subcutaneous nodules and lymphadenopathy disappeared after four weeks.

Present condition (14 weeks after cessation of treatment).—Weight (15·2 kilos) 2 st. 5 lb. 6 oz. General condition excellent. Hb 92%; R.B.C. 4,270,000 per c.mm.; W.B.C. 8,650 (lymphos. 46, immature lymphos. 2, polys. 48, monos. 4%). Platelets 260,000 per c.mm.

Sternal puncture: 3% abnormal forms of lymphocyte series.

X-ray long bones: Marked sclerosis of epiphyses.

? **Polyneuritis: For Diagnosis.**—A. P. NORMAN, M.D. (for C. F. HARRIS, M.D., F.R.C.P.).

Brian C., aged 4 years.

History.—Admitted 26.4.49 with weakness in right leg for four months. Unable to walk or stand for two months or to sit up for six weeks.

Family history.—Seventh child. First and third children died aged 4 years from some acute cerebral hæmorrhagic disease.

Examination.—Weakness and wasting of all limbs. Reflexes diminished. Muscle tone diminished. No sensory loss. Unable to stand or sit. Circumference of skull 19¾ in.

Investigations.—C.S.F. Pressure 150 mm. R.B.C. 50. Polys. 20, lymphs. 20. Pr. 90. Chl. 770. Sugar 50 mg.%

X-ray skull normal. Mantoux 1/1,000 negative. W.R. negative.

Urine: Hæmatin and porphyrin negative. Lead 80 mg. per litre (normal).

E.S.R. 6 mm. in one hour. Blood-count normal.

3.5.49: C.S.F. Polys. 2, monos. 6. Pr. 70 mg. Sugar 57 mg. Colloidal Gold curve 000,000.

8.8.49: C.S.F. Cells 4. Pr. 100 mg. Chl. 740 mg.

20.9.49: C.S.F. Clear. Cells 8. Pr. 400. Sugar 53. Chl. 730 mg.%

18.10.49: C.S.F. (lumbar). Cells 8. Protein 450 mg.%

Blood calcium 9·3 mg.%

Progress.—Generalized flaccid paresis of all limbs. No sensory loss. Very irritable. Erythematous rash on arms. Later gradual improvement. Slight irregular pyrexia, 99–100° F. at times with diminishing frequency. Pulse 110–130.

Discharged 30.8.49.

Readmitted 20.9.49. Very irritable. Head circumference 20 in. Pupils dilated. Bilateral facial weakness. Wasting and weakness of limbs. Absence of deep reflexes. Respirations became irregular and alternately deep and very shallow with occasional periods of apnœa. Never incontinent.

Progress.—No significant change.

Congenital Indifference to Pain.—W. ROE, M.B., B.S., D.C.H. (for D. G. LEYS, M.D.).

M. P., female, born 26.7.48. Admitted hospital July 1949 for failure to gain weight, and bronchitis. Mother previously three years in mental hospital. Father high-grade defective. Child was full term, normal pregnancy and delivery. Birth-weight 9½ lb. Pneumonia at three months.

On admission.—Several indolent ulcers of hands due to the child's practice of biting her fingers. Poor nutrition, hypotonia, pallor, angular stomatitis, ulcerated tongue, rhinitis.

At 15 months this child could stand, played actively with toys, spoke no words, and although probably mentally retarded was not grossly defective. The head was small (circ. 15¾ in.). All forms of painful stimuli failed to produce the usual response; they seemed merely to amuse her. No signs were found suggesting any involvement in the rest of the nervous system, nor were there other congenital defects. Wassermann reaction negative.

Diagnosis.—Congenital indifference to pain, probably the result of cerebral agenesis.

[*November* 3, 1949]

MEETING AT THE NATIONAL HOSPITAL, QUEEN SQUARE, LONDON, W.C.1

Juvenile G.P.I.—J. PURDON MARTIN, M.D.

B. T., girl, aged 6 years.

Complaint.—Progressive speech disturbance and dementia—for six months.

Family history.—Second child. One sister, five years older, normal.

Past history.—Normal progress up to the age of 5.

History of present condition.—Illness started with fit eighteen months ago preceding an attack of measles. A few months later progressive dementia noted with temper tantrums, sleep disturbance and speech disturbance.

On examination.—Marked retardation, labile mood, dysarthria, pupils dilated with poor reaction to light, bilateral ptosis. Plantar responses extensor.

Investigations.—C.S.F. 8 lymphocytes, protein 60 mg. per 100 c.c. Lange 5555432100. W.R. positive 4442 (20 units).

Hyperostosis Frontalis Interna and Calvariæ Diffusa with Surgical Relief of Severe Headache (also Bilateral Scalenus Anticus Syndromes).—COLIN EDWARDS, M.R.C.P.

Female, aged 48.

Family history includes epilepsy in mother, "convulsions" in childhood in a sister and obesity in both parents and a sister.

Patient's history.—Menarche at 8. Obesity always, but moderate until partially immobilized by phlebitis in legs at 31 and by cellulitis in leg and osteomyelitis of tibia at 36 when she also had 8 months' amenorrhœa. 10 stones at 21 years. 16½ stones at 38 years, obesity generalized over trunk and limbs. Headaches since a young girl and at 38 had them about once a

FIG. 1.—Shows calcification in falx, varying depth of frontal hyperostosis and right subtemporal decompression.

FIG. 2.—Shows marked internal frontal hypero stosis with deep pit. Outline of sella normal. [Diffuse hyperostosis in parietal area.

fortnight. B.P. then 160/100. At 38 C.N.S. examination was normal; C.S.F. analysis normal and blood W.R. neg. Blood calcium was 9 mg./100 c.c. and glucose tolerance curve slightly flattened. Skull X-ray (Figs. 1 and 2) showed the changes listed in the title, also calcification of falx but a normal sella.

From the age of 38 to 42 she suffered increasingly from severe intermittent headache, sometimes with vomiting and accompanied by loss of vision for twenty minutes with flashes of

light as it returned. Her visual acuity at 42 years was diminishing rapidly and her fields, normal at 38, were markedly contracted.

The picture throughout these years was complicated by a smouldering osteomyelitis in her tibia. Between 42 and 43 years of age, however, her vision deteriorated further with severe headache and vomiting. Optic foramina were radiologically normal.

A right subtemporal decompression was done in April 1944 (patient 43 years). It showed an abnormally thick, hard, brittle and vascular temporal bone with an irregular inner surface to which vascular dura was adherent at many points. For a year her headaches were much less severe. They then began to increase again and she had an attack of loss of consciousness without warning. Menorrhagia became very severe and at 45 years of age a radium-induced menopause eased the headaches somewhat. At 46 years a right scalenus anticus syndrome developed and was relieved by operation. At 47 years the headaches having grown pitiably severe, a left frontal decompression was done. It showed a thick bone with no evident diploe and with a craggy under-surface to which the dura was adherent at many points. Dura and brain were drawn up into one particularly deep pit at the frontal pole. It was stripped and the bone replaced. Relief from headache has been marked, and those which have since occurred have been dull and usually related to emotional stress. In the ten months immediately after operation she had occasional attacks of giddiness and one of loss of consciousness but for a year now headache and other symptoms have been slight.

Her B.P. has steadily risen from 160/100 to 230/120 in eleven years. She now has some features of a left scalenus anticus syndrome.

Birth Injury of Left Arm Showing Crossed Re-innervation from Phrenic Nerve into Nerves Supplying Biceps, Extensor Digitorum Communis and Other Muscles.—FRANK SARGENT, M.D.

L. C., male, aged 18 (carpenter).

Has difficulty in holding his work with his left hand because of weakness of the left arm and hand, especially wrist-drop, dating from birth. It was a difficult labour, as he was a 14 lb. baby but no instruments were used.

On examination.—Left arm: no sensory loss; absence of arm reflexes (present on the right); weakness and wasting of most muscle groups corresponding to a lesion extending from C3 to C7 inclusive. Wrist-drop is marked but the extensors of the forearm felt elastic and healthy, and once during examination there was seen spontaneous extension of the fingers, which was attributed to a trick movement using lumbricales but, in view of the later EMG findings, it may well have been due to a deep breath. The clinical impression was that the lesion was less severe than the disability suggested. No Horner's syndrome seen, but left palpebral fissure is narrower than right.

Electrical tests by Dr. P. Bauwens indicated that the only muscle severely paralysed was the left extensor carpi radialis. Needle electrodes inserted into biceps and extensors of forearm elicited spontaneous motor unit potentials in time with respiration, and when the patient was told to take a deep breath, bursts of motor unit activity were recorded.

The conclusion is that severe traction injury at birth caused tearing of nerve roots C3 to C7, and that subsequently crossed re-innervation occurred from phrenic roots to the Schwann tubes to biceps, extensor digitorum communis, &c. This would explain the apparent integrity of these muscles in spite of severe loss of power and also, of course, the effect of respiration on the action potentials.

Two similar cases of crossed re-innervation of the phrenic to muscles in the arm have previously been seen in Dr. Bauwens' clinic.

Myoclonus of Palate, Pharynx and Larynx.—A. B. KINNIER WILSON, M.R.C.P., for F. M. R. WALSHE, O.B.E., M.D.

W. C., female, aged 61.

Family history and past history.—Non-contributory.

Present illness.—Fronto-occipital headaches, almost daily at the beginning of 1948. Sudden loss of consciousness early one morning in July 1938 and has an amnesia for a month. She was admitted to St. Mary Abbots Hospital, where it was stated that she was semicomatose, had nystagmus—slow to the right, rapid to the left—right-sided ataxia of cerebellar type and dysarthria. The C.S.F. was heavily blood-stained. Later she was seen to have a divergent squint and some drooping of the left corner of the mouth. She became markedly euphoric. She had considerable vertigo on sitting up. This has gradually improved, but it is still enough to make walking difficult.

Since the ictus she has only had one headache.

On examination.—Very slight slurring dysarthria. Nystagmus in all directions, most on looking to left. Palate rises in the mid-line, but there is a constant 3-second myoclonus of both sides of the palate, pharynx and larynx. No cerebellar signs in the limbs, but gait is

wide-based and ataxic. Reflexes: right biceps diminished, right triceps and arm absent from old injury to elbow. Abdominals absent, otherwise reflexes normal in all respects. No sensory loss.

It was suggested that this was a lesion of the upper end of the central tegmental tract near the third nerve nucleus, due to a petechial hæmorrhage.

Bilateral Sacral Plexus Lesion—Polyarteritis Nodosa.—GERALD PARSONS-SMITH, O.B.E., M.D.

Man, aged 44.

Past history.—October 1948: Primary syphilis (W.R. ++; treponema isolated) treated with complete course of arsenic, bismuth and penicillin which produced normal serological reactions. 1930: Malaria. 1924: Typhoid.

Family history.—Father died of disseminated sclerosis.

History of present complaint.—May 1948: Gradual onset of lassitude and excessive malaise. 3.6.49: Sudden attack of severe upper abdominal pain lasting twelve hours; associated with fever and severe frontal headache.

15.6.49: Dull aching pain in joints of right upper limb, lasting three days. Four days later sudden onset of pain of left sciatic distribution; this improved over a period of six weeks leaving some numbness of dorsum of the foot. He continued to feel very run down and lost weight. During this period he had two attacks of very severe abdominal pain similar to his first attack.

12.8.49: Acute onset of right foot-drop with blunting of sensation over the outer side of leg. Admitted to St. George's Hospital on 7.9.49 under Dr. H. Gainsborough and Dr. J. R. Nassim, to whom I am indebted for permission to show this case. Stated he had some blurring of vision in both eyes for three days about this time.

Present condition.—Protracted fever around 100° F. Lost 2 stones in weight. Except for some generalized arteriosclerotic changes and persistent tachycardia his cardiovascular system shows no abnormality. B.P. 140/80.

Nervous system.—Cranial nerves and brachial plexus normal. Severe pain in the muscles of both legs. Both thighs are wasted, 1 in. more wasting on the right. Muscle power diminished, especially in right anterior tibial muscles. Right-sided foot-drop and weakness of right plantar flexors. Knee-jerks present, ankle-jerks absent. Patchy sensory loss in right L.5 distribution, hyperæsthesia of soles of both feet, sensation otherwise normal.

Investigations.—Blood-count: R.B.C. 3,700,000; Hb 77%; W.B.C. 17,900 (polys. 85%, lymphos. 9%, monos. 4%, eosinos. 1%, basos. 1%). E.S.R. 37 mm. in one hour. Urine: red cells and granular casts. Stools: positive for occult blood. C.S.F. normal.

Pulsometer curve shows a complete R.D. of the right tibialis anticus muscle.

I.V.P.: normal excretion.

Muscle biopsy: R.tib.ant. (Prof. Theo Crawford): Endarterial proliferation of the small vessels with perivascular collections of inflammatory cells. In places there is fibrinoid necrosis of the media, and the picture is characteristic of polyarteritis nodosa.

Comment.—The sudden occurrence of the neurological symptoms in the lower limbs exemplifies the vascular basis of the peripheral neuritis in polyarteritis nodosa.

Boeck's Sarcoidosis of the Nervous System.—DENIS WILLIAMS, M.D.

G. M., male, aged 39. Bank clerk. Married, with two healthy daughters. Family and previous medical histories are not contributory.

History.—The patient was in excellent health until May 1948 when his left arm became clumsy. Two months later, attacks of extensor rigidity in left leg began on climbing stairs. These symptoms persisted virtually unchanged until June 1949, although he had two attacks of loss of consciousness lasting some hours in December 1948 and April 1949, the latter preceded by a motor dysphasia. In June 1949 his left leg began to go into rhythmic clonus, in attacks lasting twenty to thirty seconds and followed by transient weakness. Two months later he experienced two types of attack: one in which he suddenly fell backwards recovering immediately; the other of clonic movements simultaneously affecting the left face, arm and leg without alteration of consciousness. He had no cough, his weight was steady, there were no skin lesions and he had no symptoms referable to other systems.

On examination.—The patient was normal mentally, and his intellectual performance was average but was not thought to be up to the expectation for a man of his background.

The cranial nerves were normal except for a slight pallor of the right optic disc. There was a mild left hemiplegia, involving arm and leg equally with slight increase in all tendon reflexes and an extensor plantar response. The abdominal reflexes were symmetrical. There was inco-ordination falling away and rebound, with an irregular intention tremor on the left side, as well as the hemiplegia, and it was clear that he had a combined cerebellar and pyramidal lesion on that side. Sensation was perfectly normal.

Heart normal, B.P. 150/90.

No abnormal signs were found on examination of the chest and there were no enlarged glands.

Very frequent attacks involving the left side of the body in tonic and clonic movements were observed in hospital. They lasted for about ten to twenty seconds and included a slow tonic contraction of the arm outwards and upwards.

Investigations.—Blood-count: R.B.C. 5,410,000 per c.mm.; Hb 116%; C.I. 1·07; W.B.C. 4,000 per c.mm. (polys. 62, lymphos. 34, monos. 1, eosinos. 3%).

E.S.R. 1 hour 5 mm., 2 hours 13 mm.

Blood proteins: Total protein 7·35 grammes %. Albumin 3·4 grammes %. Albumin: Globulin 1 : 1·16.

Cerebrospinal fluid: Pressure 180 mm. Free rise and fall. Clear and colourless. Cells—none seen. Protein—0·07 gramme %. Nonne Apelt weak positive. Pandy positive. Lange—0001110000.

W.R. negative in blood and C.S.F.

Mantoux reaction negative 1 : 10,000 and 1 : 1,000. No tubercle bacilli were seen in repeated examination of sputum, and in culture of gastric washings.

The electro-encephalogram was recorded on two occasions in Nottingham, where it showed epileptic discharges and a focal abnormality in the *left* temporal lobe. These observations were confirmed. The report (18.10.49) read "The E.E.G. is abnormal and repeated epileptic discharges occurred. These appeared to arise in the *left* hemisphere with occasionally a phase reversal in the temporal aspect of the frontal lobe, somewhere about the Sylvian point. This observation is the same as that which was made earlier at Derby. I cannot find any evidence of a right-sided parietal lesion to account for his left-sided tonic attacks."

X-rays of the chest (18.10.49) were reported upon as follows: "There is an irregular coarse mottling present in both lung fields and both hilar shadows are prominent. The appearances are unusual and are consistent with sarcoid changes. There is pleural thickening in the lower part of the oblique fissure." Previous X-rays reported upon in Derby in the summer had led to the diagnosis of Boeck's sarcoidosis.

Ventriculography carried out on two occasions by Mr. Clark Maxwell in Derby showed a normal ventricular system.

X-rays of the hands showed small cyst-like areas in the heads of both first metacarpals.

Liver biopsy was contemplated but was not carried out owing to the high level of the liver dullness.

There was general agreement that the clinical picture and the X-ray appearances were those of sarcoidosis. In the central nervous system lesions were present in both cerebral hemispheres, as shown by the attacks, the hemiplegia, and the E.E.G. abnormalities; in the left cerebellar mechanism, and probably also in the right optic nerve. Involvement of the central nervous system in Boeck's sarcoidosis is uncommon but has been described on several occasions.

Hereditary Perforating Ulcers of the Foot.—REGINALD KELLY, M.D., for DENIS WILLIAMS, M.D.

E. P., aged 24.

Family history.—Younger brother, mother and maternal uncle, maternal grandmother and great-aunt all suffered from the same disease.

Enuresis until the age of 15. First ulcer appeared at age of 21; since then recurrent, usually painless, penetrating ulcers on under-surface of both great toes, right third toe and right fifth toe with osteomyelitis of the proximal and terminal phalanges of the right big toe. No abnormalities of sensation or gait noticed by patient.

On examination.—Both big toes are enlarged and indurated, right more than left. On both there is a deep ulcerated area, punched out and dry on the left, ragged with a dirty, wet slough at the base on the right, with no normal granulation tissue. The ulcers are painless and there are similar ulcers of the same dry type as the left on the third toe of the right foot.

Loss of all forms of sensation on periphery of both feet with secondary level in stocking distribution on both legs up to mid-calf level below which there is a mild impairment of sensation. Pathological sweating at level and distal to both ankles; a flair reaction is obtained within the area of sensory impairment. Tendon-jerks preserved but ankle-jerks considerably more sluggish than knee-jerks.

Investigations.—X-rays: Spine, no abnormality; feet, osteomyelitis of proximal and terminal phalanges of right big toe.

C.S.F. normal. W.R. negative. E.M.G.: the small muscles of the medial border of the soles of both feet and the left tibialis anticus were examined; only normal voluntary action potentials were seen, there was no spontaneous activity and nothing to suggest a lower motor neurone lesion in the feet.

Section of Obstetrics and Gynæcology

President—LESLIE WILLIAMS, M.D., M.S., F.R.C.S., F.R.C.O.G.

[*December* 16, 1949]

DISCUSSION ON STRESS INCONTINENCE OF URINE IN THE FEMALE

Mr. Charles D. Read (London): In this Discussion we shall consider stress incontinence only. It is emphasized that the subjects of urge incontinence and the incontinence associated with neurological lesions are excluded.

The exact mechanism of stress incontinence is not completely known. It would appear that the nerve supply to the sphincter mechanism is intact, but it would also appear that when the bladder neck descends on straining, this bladder-neck control mechanism becomes defective. The evidence is overwhelming that the actual urethra itself plays little part in control. Terence Millin demonstrated this bladder-neck descent in a series of cystographic studies, and, furthermore, cystographic post-operative studies of operatively cured cases reveal little or no bladder-neck descent.

The structure supporting the bladder neck appears to be the pubo-cervical musculofascial layer and there is evidence that the tone of the pubo-coccygeus portions of the levatores ani muscles exerts an important influence on this descent. Kegel has suggested that on occasions the pubo-coccygeus muscles are denervated by the over-distension produced by the passage of the fœtal head. This over-distension is especially evident when the fœtus is large and when the occiput is posterior. He suggests that the inelastic nerve fibres to the muscles are damaged with resultant defective nerve supply of a variable percentage of muscle fibres of the pubo-coccygeus muscles and his new ingenious instrument—the perineometer—is designed to enable the patient to increase levator tone by active contractions against the instrument. The perineometer consists simply of a rubber obturator which fits the vaginal canal. The obturator is connected to a manometer of large excursion and active levator exercises are instituted for ten minutes thrice daily over a period of three weeks. It is really a form of physiotherapy. For the first week there is usually little impression on the manometer, but, with persistence, variable pressures are registered, and by the end of three weeks the manometer registers usually anything between 60 and 100 millimetres of mercury pressure. The instrument is especially useful in recent post-partum stress incontinence. It is obviously an instrument for use in cases associated with genital relaxation rather than prolapse. It does not cure all cases, but is worth a trial in all recent post-partum patients and in those with moderate relaxation. If the patient exhibits a demonstrable utero-vaginal prolapse, surgery is obviously indicated.

It can be accepted that in cases of prolapse with or without incontinence treated by the routine Manchester procedure or by vaginal hysterectomy and repair there is a relatively high cure rate of the prolapse with a relatively low cure rate of the incontinence, and it is essential to implement either method of surgical treatment by some special procedure directed towards the cure of the incontinence. The Marion, Kelly and Bonney procedures of sub-urethral repair will cure some, but by no means all of these patients, and various observers have assessed the cure rate of these procedures as between 75% and 95%. Our experience is that the lower figure is the more accurate. Kennedy and Joshua Davies of

the Women's Hospital, New York, use much more extensive procedures with wide and free exposure of the urethra, bladder neck and base, and a careful fascial repair, and they report a 90% cure rate. Reddington of London uses a series of simple mass ligatures after the free exposure and mobilization of the urethra and bladder neck, the effect of which is to elevate and fix the bladder neck at a much higher level.

Pacey, after a wide dissection and mobilization and a careful fascial repair, approximates the medial borders of the pubo-coccygeus muscles in addition. Ingelman-Sundberg of Sweden divides the pubo-coccygeus muscles and actually crosses them.

It may here be pertinent to mention the distressing cases of stress incontinence which persist after an otherwise successful repair of a vesico-vaginal fistula which has involved the bladder neck. At the time of repair, after closure of the fistula, attempts should be made to attain elevation and fixation of the bladder neck. These attempts are often not completely successful owing to paucity of surrounding tissue and tension. Subsequent vaginal repairs tend to be hazardous, and sling procedures perhaps more so in that there is the danger of re-opening the fistula. Wilfred Shaw has recently suggested the interposition of the bulbo-cavernosus muscles as in the Martius technique in such cases.

Of all the purely vaginal operations, my small experience of the Pacey operation has convinced me that in my hands this is the most effective procedure I have yet employed by the vaginal route.

Whatever method be employed there will remain a residuum of failures of cure by the vaginal route, and these failures constitute a fascinating and interesting group. The choice of treatment lies between a repeat vaginal attempt and some more extensive procedure involving a purely abdominal approach or a combined abdomino-vaginal approach.

The Aldridge and Studdiford operations are the best known of the combined abdomino-vaginal sling procedures, and I have reserved these for patients in whom there has been a recurrent cystocele with severe incontinence after an otherwise successful repair for utero-vaginal prolapse.

Perrin of Lyons and Everard Williams of London have advocated bladder-neck suspension to the periosteum of the back of the pubis and report good results. Marshall, Marchetti and Kranz of New York have described cervico-cysto-suspension by the abdominal route.

Wilfred Shaw has advocated the insertion of a fascial sling suspending the bladder neck and urethra by a strip of fascia lata supported above by the pubic bones, which are drilled for the purpose.

My own interest in the failed vaginal group has been in the Millin retropubic sling operation, which is a purely abdominal retropubic procedure using aponeurotic straps from the abdominal wall.

To June last I performed 126 Millin sling operations; the results are as follows:

TABLE I.—AGE INCIDENCE

(Pulmonary embolus 10th post-operative day)

TABLE III.—CAUSES OF FAILURE

(1) Insufficient elevation of bladder neck	8
(2) Severance, by sling, of urethra from bladder neck	1
(3) Diffuse retropubic sepsis	3
(4) Massive retropubic hæmatoma	1

To sum up the position as I see it at present, to cure stress incontinence, elevation and fixation of the bladder neck are the prime necessities. In certain cases of recent post-partum incontinence with mild degrees of genital relaxation some may be cured, or at least improved, by the use of the perineometer.

If surgery be embarked upon the primary procedure should be a purely vaginal one, and it must ever be remembered that the first attempt should be the successful one, and consequently it should be adequate. In the failed vaginal case some more extensive procedure is indicated, and it would appear that some form of sling operation offers a reasonable hope of cure.

I hazard the opinion that Mr. Millin's latest sling operation from its simplicity and effectiveness will make these more extensive sling procedures unnecessary.

I close with the conviction that a sling operation is rarely justifiable as a primary procedure, and must be reserved for use after failure of cure by the vaginal route.

Professor J. Chassar Moir: *The Aldridge sling operation.*—Some four years ago, in 1945, I found myself championing the cause of the Aldridge sling operation before this audience and comparing it, pro and con, with the Millin sling operation; later (1947) I pursued the subject further before a meeting of the Edinburgh Obstetric Society.

My views on these operations remain substantially unaltered. The end-results of both are very similar, and the choice of either depends on the opinion of the surgeon regarding the ease and safety of the respective techniques. In favour of the Aldridge operation one can say that the important dissection round the upper urethra is done by direct approach, and by a route familiar to the gynæcologist; there is therefore comparatively little danger of serious injury to urethra or bladder. In favour of the Millin operation one can say that the approach is entirely by one route—the abdominal—and that the operation can be performed quickly and without need for altering the patient's position throughout. In making his choice, much will depend on the experience of the operator with the type of technique used. I feel bound to say, however, that a surgeon new to this class of work is likely to get good results with less risk to his patient if the Aldridge technique is selected.

Comment on the ingenious Millin No. 2 operation now presented is idle until we have had experience. Meantime let us congratulate Mr. Millin on his enterprise, and on having—in more senses than one—broken new ground.

As previously emphasized, I hold that sling operations of any variety should be reserved for those cases in which simpler surgery has failed to effect a cure—the case in which the surgeon, so to speak, has "worked his thunder," but in which stress incontinence of urine continues as before. In consequence of this conservative attitude I and my assistants, Mr. Scott Russell, Mr. Gordon Lennon, and Miss J. R. C. Burton-Brown, have performed the Aldridge operation (or some simple modification) on only 26 cases to date. It should also be mentioned that many of these operations have been done on very unpromising material. For many years I have had a special interest in vesico-vaginal fistula work, and have had a great many "intractable" cases of this injury sent from various parts of the country. Some of these patients have suffered extensive destruction of the upper part of the urethra and the sphincteric region of the bladder; and although in every case the fistula has been closed, stress incontinence of varying degree has sometimes persisted. Some of these patients have later been treated by the Aldridge operation; and in judging the results presented in the following table allowance must be made for this particular type of case, which in no circumstances can be classed with those in which the bladder and urethra are anatomically normal.

ALDRIDGE SLING OPERATIONS
Total—26 Cases

	No vesico-vaginal fistula	Vesico-vaginal fistula
Highly satisfactory	11*†	7
Substantially improved	1	1
Moderately improved	1	2
No change	1‡	2

* One patient untraced; when seen four weeks after operation the result was excellent.
†One patient, an elderly woman, died three months after operation. Multiple pulmonary and coronary emboli found; operation site free from any evidence of sepsis.
‡ Not a case of true stress incontinence.

Nine of the 26 patients cases were observed for periods of three to six years; there was no relapse of symptoms. One gets the clinical impression that if improvement is maintained for six months, the effect is permanent.

In conclusion, let me again stress the fact that the Aldridge technique, although somewhat time consuming, is simple, and is free from high risk of damage to bladder or urethra. In suitably chosen cases this particular form of sling operation can give excellent results.

REFERENCES

MOIR, J. C. (1945) *Proc. R. Soc. Med.*, **33**, 661.
—— (1947) *Edinb. med. J.*, **54**, 368.

Mr. Terence Millin (*Abridged*): The spate of "new" operations, which have flooded the journals during the past few years would appear to indicate a not untimely recognition of an ill-founded complacency with past results.

In 1946 Mr. Everard Williams stressed the necessity for urological and neurological investigation in all cases (*Proc. R. Soc. Med.*, **40**, 361). How often, even to-day, is that excellent precept carried out?

The problems before us are (*a*) how to prevent or minimize the incidence of the "failed case"? and (*b*) how to deal successfully with it, should it occur?

Everyone is agreed that if genital prolapse or evidence of marked pubo-cervical relaxation is present then some form of vaginal repair should be undertaken, at least in the first instance. Whether such should be perpetrated as often as five times, as was the case in 3 of our patients subsequently cured with a sling, seems doubtful. At the risk of being held presumptuous, I must say that I cannot but believe that a more careful urological study of these cases pre-operatively along the lines we shall suggest in a few moments might indicate a group which would be helped by an additional buttressing—Aldridge sling if you like—added to the repair. I should also like to go on record as being sceptical of lasting results in the Pacey-Treahy procedure where the approximation of pubo-coccygei is under extreme tension. (Slides illustrating the speaker's objections were then shown.)

Still on a destructive note, may I say a few words about some other methods in use to-day. The various "sling" techniques—Goebell-Stoeckel, Aldridge, Studdiford, Delinotte, Marshall and our own—have now been practised sufficiently long to have established that the *principle* will give satisfactory results provided that the technique has been correctly performed and that no post-operative infective phenomena have intervened. Faulty technique is by far the commonest cause of failure. Too often undue elevation of the bladder neck transforms a case of stress incontinence into one of absolute or relative retention. Too often a faulty passage of the sling occurs and cases have been met where it has been passed through bladder, urethra or vagina. The retropubic type of operation, whether it be Marshall's or mine, would appear to be unduly difficult for many operators particularly when they are infrequent explorers into the cavum Retzii.

The "sling" operations carried out *per vaginam*, such as the Aldridge, would seem to be more readily performed by most gynæcologists but these are not immune from occasional distressing sequelæ such as infection carried into the *undrained* retropubic space from an infected vagina. It is also theoretically undesirable to have the unabsorbable strap sutures in close proximity to the vaginal suture line.

Of the recently advocated "bone-boring" procedure, the consensus of opinion is that it is one of the most ill-conceived surgical procedures in living memory. To maintain that swabbing of a cavity so commonly infected as the vagina with any known antiseptic can render it a fit area through which to open up cancellous bone with its well-recognized poor resistance to infection, even in these days of antibiotics, would seem to be abject heresy.

The Everard Williams procedure, little more than a substitution of catgut for the silk employed in the Perrin cervico-cystopexy, which has not given lasting results, at least on the Continent where it has been tried extensively, does not appeal to many.

Now to attempt to be constructive. Before planning an operation for the relief of severe stress incontinence it is surely essential to be fully conversant with the exact pathology present. The degree of pubo-cervical relaxation, as is well known, bears no relationship to the extent or even presence of urinary loss. One ought to know the precise dysfunction of bladder and urethra, and I believe that this cannot be assessed sufficiently accurately by clinical means but can be readily demonstrated by our vertical cystographic technique already described elsewhere [1].

May I remind you briefly of the commonest urological abnormalities found in our cases?

(*a*) "Funnel" deformity of the vesical outlet: (i) Congenital, (ii) Neurogenic, (iii) Post-operative.

(*b*) Ptosis of the bladder neck on raising the intra-abdominal pressure.

(*c*) Loss of the normal anterior concave curve of the urethra.

(*d*) Abnormal dilatation of the whole urethral canal.

(*a*) I shall not consider the problems of treatment in the first two groups as they are of urological rather than gynæcological interest. The third group, however, is an important one in that it includes those cases of stress incontinence developing after a successful closure of a trigonal vesico-vaginal fistula. The reason is not far to seek; the cure not so simple. Either subsequent vaginal interventions or a retropubic sling may jeopardize the scar of the healed fistula. I submit that our new sub-pubic sling may be the answer.

(*b*) Cystography will demonstrate in a high proportion of cases the vesical neck descent on raising the intra-abdominal pressure by coughing, &c. Some care is necessary in interpreting these cystograms.

(*c*) The oblique view of the vertical cystogram will frequently reveal a loss of the urethral curve—a point noted clinically many years ago by Victor Bonney.

(*d*) Marked urethral relaxation is revealed by loss of the opaque medium alongside the No. 20 Ch. catheter commonly used for the cystogram.

The latter two abnormalities may not be common but I have 3 personal cases where an Aldridge sling operation performed elsewhere had failed to cure the incontinence, though supporting the bladder neck, and in whom a simple correction of these by our sub-pubic approach gave an excellent result.

Sub-pubic Approach to the "Failed Case"

I shall now describe my sub-pubic approach to the problem of the "failed case" where no marked pubo-cervical relaxation is present. It would appear to have the merit of simplicity, both for patient and operator. It still retains the "sling" principle when a descent of the bladder neck has been shown to occur and at the same time allows us to correct, if present, the loss of the urethral curve and an undue laxity of the urethral canal.

The operation briefly consists in passing a sling under the bladder neck by a sub-pubic approach. The sling has, to date, consisted of a 20 cm. strap of fascia lata obtained either by means of a stripper or by a deliberate incision. In all probability a similar length of stout kangaroo tendon or similar material would suffice. Having obtained the strap, the patient is placed in the lithotomy position and whilst the operator is working below an assistant makes a short 5–8 cm. transverse incision above the pubis to expose the anterior rectus sheath. A No. 20 Ch. 5 c.c. Foley catheter is passed along the urethra and the balloon dilated to capacity. The bladder is allowed to empty and the balloon drawn down until it impinges against the vesical neck. A short incision is now made between clitoris and external urinary meatus, closer to the latter, and deepened for $\frac{1}{2}$–1 cm. until the inferior leaf of the urogenital diaphragm is met. A few veins of Kobelt's plexus will be sectioned. The hiatus through which the urethra emerges will be clearly seen and this is now enlarged by passing a closed pair of Mayo's scissors along the dorsal surface of the urethra into the hiatus and then opening the blades. The right index finger is now passed through the hiatus deep to the sub-pubic arch into the retropubic space and the bladder neck pushed back gently from the pubis. If the venous ooze is troublesome a temporary small pack is placed deeply whilst the sling is placed sub-urethrally. The operator's left forefinger, ensheathed in a sterile finger-cot is placed in the vagina and pressed forwards, so presenting the urethra with its contained catheter into the field. A Morley's hernia needle or Millin-Read forceps is now gently insinuated under the urethra immediately below the bladder neck (identified by the balloon of the catheter), the jaws are slowly opened so creating the tunnel. One end of the strap is seized and drawn through. Utilizing a Bozeman's uterine packing forceps each end of the strap is passed into the little

wound deep to the pubis, traversing the retropubic space and corresponding rectus muscle and made to present against the overlying aponeurosis. The assistant makes a small buttonhole incision in the sheath and seizes the end of the strap with a pair of Kocher's forceps. Each end of the strap is then drawn upon avoiding undue tension. It must be stressed that, as in all sling operations, the aim is *not* to elevate the bladder neck but rather to prevent its descent when the intra-abdominal pressure is raised. By means of two chromic catgut sutures the two cavernous bodies are drawn together anterior to the urethra so restoring its normal curve and the little incision in the fourchette closed by means of 3 fine catgut sutures. If the urethra has previously been shown to be unduly dilated a narrow strip of its anterior wall is resected and the canal closed with a fine continuous plain catgut stitch. It now remains only to fasten each strap to the buttonhole in the rectus sheath, with silk or nylon, and suture the two ends of the strap together as an additional security. The skin is closed.

The operation can be completed in 20 minutes. The catheter is left in situ for 48 hours. The patient is allowed out of bed the next day and can leave hospital as soon as the skin sutures have been removed.

I can only claim to have performed the operation 18 times. The theoretical soundness of the procedure, the uniformly good immediate results, the minimal disturbance to the patient and the short hospital stay, make it, I submit, worthy of trial. There should be little risk of perforating the vagina in passing the forceps to create the sub-urethral tunnel. In the remote chance of this occurring, the intra-vaginal finger would detect the error and an immediate closure of the vaginal mucosa could be effected. Retropubic space venous ooze can escape by dependent drainage between the interrupted fourchette sutures. Should undue elevation of the bladder neck be caused by the sling this could be remedied by the simple expedient of re-opening the small suprapubic skin incision, cutting the supporting nylon sutures and refixing the sling less tautly.

I would suggest that this operation would appear to fulfil the accepted canons of reconstructive surgery: (1) Restoration of function, (2) Re-establishment of normal anatomy. (A coloured film of this operation was then shown.)

REFERENCE

[1] MILLIN, T., and READ, C. D. (1948) *Post. Grad. med. J.*, **24**, 51.

Mr. H. H. Fouracre Barns: *Demonstration of film of round ligament sling operation for stress incontinence.*—The film shows a sling operation in which the round ligaments are used to make the sling. The sling passes beneath the bladder neck and approximates the bladder neck to the posterior aspect of the symphysis pubis and at the same time elevates the pelvic floor.

Mr. J. J. O'Sullivan (*from the Dept. of Gynæcology, St. Bartholomew's Hospital*): *Demonstration of film:* "Shaw's Sling Operation".—Our indications for this sling operation are patients who show a downward and backwards prolapse of the urethra and bladder neck and a patulous external meatus, and in whom true stress incontinence can be demonstrated in the examination room. Also all cases of stress incontinence following on previous vaginal operations.

We consider a new sling operation necessary because of the high recurrence rate following the use of other slings, in our hands, and also because of the serious post-operative complications and of the technical difficulties in achieving the desired result even though the operation is theoretically sound.

A broad band is necessary as the whole urethra needs support and, what is more important, because the localized pressure produced by a narrow band on such a weak structure as the urethra produces sloughing or stricture formation with their attendant dangers such as fistulæ and renal complications. If the narrow band is not placed in its correct position immediately under the internal urethral sphincter, it does not produce a physiological cure but only alleviates the symptoms by kinking the urethra under conditions of strain. It may also cause complete retention.

Fascia lata would appear to be the ideal source of this sling as, when it is taken from the lower end of the aponeurosis, it does not stretch and is stronger than other types of fascia. It also obviates the necessity for rather long abdominal incisions and the difficulties encountered in patients who have had previous abdominal operations.

It is absolutely essential to open the anterior vaginal wall so that the sling may be placed in its correct position and to avoid blind or semi-blind dissection which, again, is a potent source of urinary fistulæ.

We regard the direction of the sling to be so important that we drill holes in the pubic bone to achieve the desired result. The urethra in its normal position is at an acute angle

to the symphysis pubis and, to replace a prolapsed urethra in this position, the sling must go through the upper end of the pubic bone near the mid-line. Also the fibromuscular ligament which passes between the anterior loop of the internal urethral sphincter and the posterior surface of the symphysis pubis acts in this direction.

An obvious criticism of this operation is that it is liable to produce clinical shock. An anæsthetist is always a better judge of the degree of shock than the surgeon who is performing the operation. Our regular anæsthetist, Dr. Langton Hewer, says that the degree of shock produced during this operation is on a par with that produced during an average vaginal hysterectomy. A deep anæsthetic is necessary.

Excessive hæmorrhage is rarely encountered and then only when the para-urethral tissues are incised. It is impossible to stop this at its source but it always stops when the sling is placed in position. No patient in this series required a blood transfusion.

We have performed 75 of these operations and the follow-up period ranges from one month to two years. Comparing the results of these two operations, the following figures would appear to be of interest.

We have performed 17 obturator operations and in 3 of these failed to cure the stress incontinence, a recurrence rate of 17·6%. We used tantalum wire gauze instead of fascia lata in 4 of these cases. They were all relieved of their symptoms but ulceration of the anterior vaginal wall occurred in 3 of these. There was 1 death in this series, a patient dying in coma as a result of uncontrollable diabetes. We have abandoned the obturator operation because of the recurrence rate. 58 pubic-bone operations were performed with one failure; a recurrence rate of 1·7%. The following post-operative complications occurred: Urinary tract infections, 4 cases. Hæmatoma of vulva, 1 case; Phlebothrombosis, 1 case. There were no cases complicated by shock, hæmorrhage, osteomyelitis or urinary fistula.

Mr. Harland Rees: If the bladder is filled with dye and a film taken whilst the patient is straining down, descent as shown on the X-ray may be due to bladder-neck descent or to the presence of a cystocele or to a combination of both, and it is, therefore, difficult to gain precise information from this type of X-ray of the relevant fact in stress incontinence, namely bladder-neck descent.

At St. Peter's Hospital during the last year we have been using another method, first suggested by the Registrar, Mr. E. M. Nanson: A Foley catheter is passed into the bladder and the bulb is distended with dye, the catheter is then pulled down gently so that the bulb is in direct contact with the internal urinary meatus. A film is taken with the patient standing but at rest, and a second film is taken with the patient in a similar position but straining down. This gives a fairly accurate measure of the movement of the bladder neck.

Mr. Rees showed a number of slides to illustrate this method.

Mr. A. W. Badenoch: As it is exceptional to see stress incontinence in the nulliparous, the majority of the cases with whom I have had to deal are referred by gynæcological colleagues, and all have had at least one reparative operation on the vagina. I first employed the Aldridge operation and later did the Millin sling. The mechanical principle is the same in each of these procedures and it is only the approach which is different. I have always been apprehensive of the danger of producing injury to the bladder and the urethra, when burrowing between these and the scarred vaginal wall. I believe the Aldridge approach is safer, but in my hands neither it nor the Millin has been sufficiently successful for me to be comfortable in accepting the considerable risk which is associated with each of them. Stimulated by my colleague Harland Rees, I have been performing a cystopexy of the type advocated by Everard Williams. It is a simple operation; there is no danger of tearing the urethra or bladder, and it works—at least as frequently as a sling operation. I have had success in one case in which a Millin operation done by me had been a failure.

Mr. B. Rickford: The first case I treated by the Millin sling operation was cured in spite of the following complication: Severe extravasation of urine into the cave of Retzius necessitated reopening the wound. The slings which had been bathed in urine for two days were gangrenous and were therefore removed. The patient recovered and the suprapubic fistula healed after three months. The stress incontinence was cured and the patient is still symptom-free three years later.

I am wondering, in view of the removal of the sling, how important is the part played by sepsis and scarring in the cure of stress incontinence by the Millin sling procedure.

Mr. Hugh McLaren (Queen Elizabeth Hospital, Birmingham): In the University Unit at Birmingham we take the view that any form of sling operation is a very serious matter for the patient, and the operation is therefore performed only when it is obvious that nothing else will effect a cure.

L. A. Cruttenden and myself have undertaken only 12 Aldridge operations in the past two years, but from this experience I think we can fairly say that the operation is relatively straightforward; certainly it is much less complicated than the procedure outlined by Mr. Millin in this Discussion.

In an attempt to limit sling operations as far as possible, we have on two occasions set out to undertake a vaginal plastic repair, to find (as anticipated) that even the most careful dissection could not produce adequate amounts of vesico-vaginal fascia. Flaps were then cut and used as in the Aldridge operation. This method of vaginal exposure, cutting of flaps and subsequent return to the vagina, requires considerable staff-work in the theatre to limit the risk of sepsis.

Mr. J. V. O'Sullivan: I have performed 6 operations similar to that described by Wilfred Shaw. I gave up the operation because 3 cases developed severe shock and because of the danger of infection in the cancellous bone.

It is necessary to teach patients, following Millin's operation, to relax to pass urine rather than to strain in the usual way. Recently I had a husband who complained that my Millin's operation had prevented his wife wetting herself when up and about, but now she wet both of them in bed as she dropped off to sleep.

My only criticism of Millin's operation is that the fascial slings are sometimes too weak. Recently I have used one broad fascial graft, instead of two as recommended by Millin, with excellent success.

Mr. W. Hawksworth: Although the operations, as demonstrated by both Mr. Read and Mr. Millin, look extremely easy the younger members of the audience should not be misled into feeling that they could perform the operation without difficulty. Those who have tried to perform a Millin sling No. 1 operation know just how difficult it can be, and therefore it should be realized that all and sundry should not embark upon this new procedure without adequate training. I recently had the opportunity in New York of discussing this operation with Dr. Aldridge, and he stated himself that on occasions it was extremely difficult to find the plane of separation between the anterior vaginal wall and the urethra, and he had sometimes found it necessary to open the fundus of the bladder so that a finger could be passed down into the urethra in order to facilitate this dissection.

There is no doubt that where some form of sling operation is necessary, the Aldridge sling itself is easier to perform than the Millin sling No. 1.

Miss Doreen Daley: A patient of mine who had had a sling operation performed by Mr. Millin in 1948, had an easy vaginal delivery of a 6½ lb. baby three months ago. She had had no return of stress incontinence when seen at the post-natal clinic a few weeks ago.

Mr. Vivian H. Barnett: The Aldridge operation has been criticized on the grounds that it necessitates abdominal and vaginal approaches, which, not being performed together, lead to a prolonged operation. By using an abdomino-perineal extension to the operating-table, strips of abdominal fascia can be obtained by an assistant while the vaginal operation is performed.

I wish to ask Mr. Millin what the objection is to passing up the strip of fascia lata by the same route that the abdominal strips are brought down in the Aldridge operation, instead of making an incision anterior to the urethra as described in his "Millin's II Technique".

Complications of Rectal Injections

By A. DICKSON WRIGHT, M.S., F.R.C.S.

THE injection treatment of hæmorrhoids which I believe was first evolved outside the medical profession has now secured a wide adoption within it. Providing an easy way out of a humiliating dilemma, it is much appreciated by the public and the profession also likes the method because it avoids an operation which even the most ingenious have found hard to make comfortable.

Like every other method it naturally has its complications and, as they are to a great extent avoidable, the preparation of this paper was thought to be worth while.

Allergic manifestations and pyrexia occasionally are encountered and this most probably was due to the oily medium rather than the 5% phenol. During the war when the medium was changed from almond to arachis oil, there were numerous complaints of dizziness and fever lasting for two or three days and occasionally the appearance of an urticarial rash. Almond oil seems to be free from these disadvantages.

Hepatic disturbances probably arise from intravenous injections with a condition of oil embolism of the liver resulting. I have had 2 cases of this, the patients being severely ill with epigastric pain and muscular guarding, a sharp pyrexia and even a rigor. In 1 case the victim was a medical man (a radiologist) and he was quite sure that he had perforated a long-standing duodenal ulcer. Radiological examination revealed no gaseous crescent and the condition got well in three days. In the other case the acute painful stage was followed by a transient jaundice and a swollen tender liver. The moving of the point of the needle during injection if the submucosal wheal does not rise should avoid this complication, which can be very alarming.

Necrosis and hæmorrhage seems to occur in cases where a second course of injections is being repeated after an interval. The previous scarring prevents even spreading of the oily fluid, so that excessive tension and blanching is produced and the mucosa undergoes necrosis. The ulcer produced being above the area of sensation, no pain is produced, but the patient notices the bloody discharge and the rectal irritability. To prevent this complication the second series of injections should be placed in the gaps between the standard pile positions and the wheal should not be completely blanched by too forceful injections. Massage of the affected area with the finger should be given after each injection is completed so as to spread the oily fluid.

The bleeding from necrosis is rarely severe nowadays, but it was serious in the old days when pure carbolic or the glycerin of carbolic was used and stories were current in past days of fatalities from this cause.

Thrombosis and prolapse of the pile mass may follow injection. This is generally the result of injecting too low in the anal canal so that the injected and later the inflamed area may prolapse. The condition produced is the well-known one which used to be described as strangulated piles and while at its height the patient is unable to think of getting out of bed.

This condition is prevented by injecting the root of the pile above where "the purple joins the pink" as it has been aptly put. Furthermore, when prolapse is a marked feature it is inadvisable to inject for fear of this complication and on general considerations as well.

A *gangrenous condition of the anal canal* occasionally occurs and I recollect one such case demonstrated by the late Mr. Simpson-Smith. Rectal symptoms sometimes occur in agranulocytosis and make the patient seek injection treatment and I felt that this was the underlying condition in this case. Severe diabetes is also a contra-indication to pile injections and old and debilitated subjects are best left alone for fear of this phagedænic condition.

Genito-urinary complications are extremely important and become the subject of litigation because they are undoubtedly the fault of the injector. They occur only in the male subject and when the anterior pile is the target of the injection.

The 10 c.c. of oil are deposited in whole or in part into the prostate, the urethral wall, or even the seminal vesicles and may lead to any of the following conditions : (1) Retention of urine. (2) Hæmaturia. (3) Oleouria. (4) Hæmatospermia. (5) Prostatic necrosis and abscess. (6) Stricture of prostatic or membranous urethra. (7) Abscess of the seminal vessels. (8) Epididymitis which not infrequently breaks down to form an abscess. (9) Testicular atrophy which may be bilateral. (10) Chronic cystitis. (11) Recurring pyelonephritis with its consequences. (12) Renal calculus as a result of chronic infection. (13) Urinary fistula in the perineum from drainage or rupture of a prostatic abscess.

Six cases of this group have been actually encountered.

Three had retention with hæmaturia; all of these recovered completely, but in two the urine became infected as a result of the catheterization. There was one case of stricture of the prostatic urethra and this patient developed bilateral epididymitis with suppuration and secondary atrophy of the testicles and chronic prostatic abscess (drained rectally) and bacilluria. This patient required periodic dilatations of the stricture and on one occasion when this was done outside the shade of the chemotherapeutic umbrella, fulminating pyelonephritis with a three-day suppression of urine resulted. He has recently died from a carcinomatous colon.

The fifth case was one of prostatic stricture with atrophy of one testicle, prostatic abscess and recurring pyelonephritis. This patient also has a urinary fistula in the perineum where the prostatic abscess ruptured.

The last case developed a renal calculus and chronic resistant bacilluria associated with prostatic abscess. This bacilluria case has resisted all attempts at cure although the renal stone has been removed.

These cases need never occur if a good view of the area of injection is obtained and the wheal is observed to rise steadily during the process of injection. For this purpose a slotted speculum such as Perrin's is the best. I believe the Kelly's speculum does not allow the wheal to develop as it should and it also prevents the anal landmarks from being seen so that the injections may be made too high. Needless to say the needle should not be pushed through any resistant tissue nor should the injection fluid be forced in against strong resistance and any complaint from the patient of penile pain or micturition desire should be a warning to stop and take bearings.

Should hæmaturia or retention occur immediately after injection, it would be a good practice to incise the tense swollen prostate through the rectum and allow the oil to escape the way it got in. I have never had the opportunity to do this as the cases which came my way were not seen until the complications were well established, two of the cases were not encountered till one year after the commencement of trouble. In one of these cases, however, the prostatic abscess was incised through the rectal mucosa with benefit.

Injections of proctocaine for anal fissure sometimes result in very extensive abscesses. It is probable that the fissure has already induced a small satellite abscess in these cases and the deposition of a quantity of oil in the vicinity results in a rapid extension of the sepsis.

It is wise before injecting these cases with oil to secure a novocain anæsthesia first and then to make a very full examination and bi-digital palpation of the perianal tissues. It is very hard to explain away this abscess to the patient, immediately after the injection for which possibly too much was promised. In a recent case I opened a most extensive ischio-rectal abscess eighteen days after a proctocaine injection for a fissure and this patient developed an endocarditis from a *Streptococcus fæcalis* for which no chemotherapy availed.

Proctocaine injections for pruritus ani may similarly cause abscesses and also necrosis of the skin with ulceration. There is a certain school which employs alcohol for these injections and they anticipate cutaneous gangrene in nearly every case.

Mr. W. B. Gabriel: At St. Mark's Hospital we seldom use anything but the 5% phenol in almond or arachis oil, and I agree with Mr. Dickson Wright that special care must be taken when dealing with the right anterior pile. Our teaching is that the best and safest proctoscope is a tubular proctoscope of the Kelly type and personally I only use the Perrin proctoscope for minor procedures such as excision of hypertrophied anal papillæ.

As regards oil-soluble anæsthetics I am sure that they should not be used for deep chronic fissures, especially when there is evidence of infection at the base, and even in the superficial fissures there is good reason to believe that equivalent relief can be given by use of surface anæsthetics such as 3% decicain or anethaine ointment rather than by deep injection of an oil-soluble anæsthetic solution with its potential risk. So far as injection therapy for pruritus ani is concerned I join issue with Mr. Dickson Wright when he says that this is a current and accepted method of treatment: I find that most cases of anal pruritus are amenable to local or general treatment, and whatever the cause may be the patients have to learn not to scratch. The responsibility for stopping the scratching habit must surely be with the patient, and I believe it is a mistake for injection therapy to be given since then the surgeon tends to take upon himself responsibility for cessation of itching and the patient underestimates the effort that is required on his part. I have not injected a case of anal pruritus now for several years.

Mr. E. T. C. Milligan: In the treatment of first and second degree hæmorrhoids we find that the injection treatment provides a safe remedy. At St. Mark's Hospital day after day and year after year in the large out-patient clinics injections are made by surgeons and their assistants and no complications are seen except, rarely, a small superficial ulcer on the mucosa giving a little bleeding but no inconvenience, and it soon heals.

Complications can be avoided if the right solution is put into the right place.

The solution is 5% phenol in almond oil in doses of 3 to 4 c.c. injected submucously into each of the three piles according to size. So safe is the injection that some venture to put as much as 10 c.c. into one large pile.

The glycerin solutions now discarded acted with intolerable uncertainty so that after injection patients sometimes had to be admitted with hæmorrhage from deep ulceration more serious than severe cases of secondary hæmorrhage after hæmorrhoidectomy. They needed local treatment together with blood transfusion. Pain, too, occurred sometimes exceeding post-operative pain.

With the decision to use only the 5% solution of phenol in almond oil, confidence in injection treatment returned, fear and uncertainty of subsequent dire complications were banished.

The place and site of injection.—The place of injection is in the submucosal space of the pile around the blood vessels. The mucosa is about 1 mm. thick so the needle should not go deeper.

A sharp stab with a lightly held and balanced needle and syringe will convey the impression through the hand that the needle has pierced the mucosa and reached the space under the mucosa. Here the needle can be freely moved with the mobile mucosa which could not be done if it had entered the muscle wall or extra-rectal tissues. The first few injected drops will balloon out the vascular mucosa and so further verify that the needle is in the right place.

The site of injection is the ano-rectal ring where the rectum ends and the anal canal begins; an easily observed locality for here a ring of mucosa first closes into the lumen of the tubular proctoscope like the shutter action in an iris diaphragm as the proctoscope is withdrawn from the distended cavity of the rectum into the anal canal. This site is the pedicle of the pile at its junction with the internal pile and further identified by the pink colour of the mucosa.

Solution injected at this locality will freely spread up into the pedicle and down into the internal hæmorrhoid as far as the intermuscular septum. This septum separates the insensitive part of the pile from the sensitive skin covering the external pile below.

Success and safety of injection depend on the knowledge of the surgical anatomy of the part and the recognition of the parts of the pile more than on the kind of instruments used.

The overlooking of co-existing lesions in rectum and colon is a serious matter.

In perianal injections of proctocaine necrosis of skin can only occur if injections are wrongly made into the skin or between the skin and the corrugator cutis ani muscle. Such a complication is not serious, the slough will soon separate and the wound will heal.

Should infection follow perianal or submucous injection, a very rare happening, it would happily be confined to the submucous and perianal spaces. The resulting abscess or fistula could easily be dealt with. Should the injections be wrongly put extra-rectally or into the ischio-rectal fossa, a serious abscess or fistula requiring extensive operations and much time in healing would result; so injections into the ischio-rectal space should be avoided.

It should, however, be stated that perianal and submucous infection and abscess are the rarest of complications; an arresting fact when one reflects on the bacterial population of the coverings through which the puncture is made.

Mr. S. O. Aylett: Following the third injection for hæmorrhoids, a colleague of mine developed acute pain in the region of the liver. Within ten minutes of the treatment the pain was severe and the patient had to retire to his bed.

Within twenty-four hours the liver had become enlarged to two fingerbreadths below the costal margin, and mild jaundice resulted. He was confined to his bed for ten days before the condition subsided.

The injection was in no way different from the hundreds performed in proctological practice. No blood was withdrawn into the syringe before injection with 5% phenol in oil, and the treated hæmorrhoids ballooned up in the usual fashion. In spite of this it seems certain that some of the phenol had entered a vein and had been carried to the liver via the inferior mesenteric vein.

Recovery from the complication has been complete.

Three Unusual Cases of Colitis Treated by Surgery

By E. C. B. Butler, F.R.C.S.

The term colitis or ulcerative colitis has often been applied to any inflammatory condition of the large bowel for which no definite cause could be found. The time has now come when the term ulcerative colitis should be reserved for those cases where the whole or distal part of the colon is involved by disease and where the ulcerated mucosa has been demonstrated at sigmoidoscopy.

Segmental areas of colitis or those infections attacking the proximal colon should, I suggest, be placed in a separate category since their prognosis differs from true ulcerative colitis; if surgical treatment is required an ileostomy is rarely needed and their response to less drastic methods is most encouraging. The following 3 cases were all diagnosed: "? ulcerative colitis" at one time or another; none of them ever showed the true sigmoidoscopic picture of ulcerative colitis.

Case 1.—Female aged 23.

History.—Twelve months' gradual onset of diarrhœa and colicky abdominal pain; she lost 2 st. in twelve months. For the last three months she had noted a lump in her abdomen.

8.6.47: She was admitted to the London Hospital with the provisional diagnosis of tuberculous peritonitis.

On examination.—A wasted girl with an irregular pyrexia up to 102° F. Stools showed no pathogenic organisms. There was a large tender swelling in the right iliac fossa. A barium follow-through meal showed a filling defect in the cæcum with spasm and loss of haustration in the proximal colon.

Operation.—18.6.47: Laparotomy. The terminal 6 in. of the ileum were thickened and œdematous to form a tube which was attached to the anterior abdominal wall; this was the lump which could be felt before operation. There were many enlarged glands in the mesentery. The cæcum, ascending and transverse colon were thickened and indurated, the remainder of the large bowel was normal.

The ileum was divided and the distal end embedded some 2 in. above the diseased portion. The proximal end of the ileum was anastomosed end to side into the pelvic colon. After operation a swinging temperature developed and an abscess became evident in the right iliac fossa. Aspiration showed 20 c.c. of pus; culture showed at various times *Staph. aureus*, anaerobic streptococci, and *B. coli*.

The abscess was treated by repeated aspiration and injection of, at first, penicillin and later 1/10 gramme of streptomycin daily for six days. At the end of this time only a little clear fluid was withdrawn and the patient's temperature was normal. She then made a quick recovery and regained her weight rapidly. Since leaving hospital she has attended the follow-up clinic every three months. She has no abnormal symptoms or signs and is able to do her work.

Comment.—This patient was probably a case of Crohn's disease of the terminal ileum which had spread into the proximal half of the large bowel. The rapid relief of symptoms following division of the ileum with anastomosis of the ileum to the pelvic colon was most striking and so far colectomy has not been required. The sterilization of the abdominal abscess by repeated injections of streptomycin was also instructive; open drainage was avoided and so was the risk of a persistent mucous fistula.

Case 2.—Woman aged 35.

History.—Eleven months' diarrhœa, intermittent pyrexia and loss of weight.

On examination.—A wasted, ill woman with an irregular pyrexia. There were no abnormal physical signs. A barium enema showed signs of inflammation of the proximal colon as far as the beginning of the pelvic colon. Sigmoidoscopy was normal to 20 cm.

In spite of general treatment and blood transfusions her condition became steadily worse.

Operation.—20.8.47: Laparotomy. Chronic inflammation of the whole of the large bowel from the cæcum to the commencement of the pelvic colon; there the disease stopped abruptly. The transition from the thick indurated bowel to normal pelvic colon was most striking. The small intestine was normal.

The pelvic colon was divided 2 in. distal to the disease and the proximal end was brought out as a mucous fistula. The distal end was embedded. The ileum was divided, the distal end was embedded and the proximal end anastomosed end to side into the normal pelvic colon.

The patient made a smooth and rapid recovery; her appetite returned and she rapidly gained weight.

Since her operation she has attended hospital every three months. Except for an irregular discharge of mucus from her fistula she has no complaints. A colectomy has not been required.

This patient evidently suffered from that form of colitis which has been well described (Crohn, B. B., Garlock, J. H., and Yarnis, H. (1947) *J. Amer. med Ass.*, **134**, 334). In their experience about 8% of colitis cases fall into this group. Diarrhœa and rectal bleeding are not prominent symptoms but constitutional reactions are often severe and a large number of these patients develop arthritis. If untreated the colitis tends to progress distally until the whole colon may become involved.

The object of surgical treatment is to isolate completely the diseased colon. Division of the colon distal to the disease is considered an essential step otherwise the infection might still creep down the bowel and could then not only invade the rectum but also the site of the anastomosis and thus invade the small gut.

If symptoms persist after the exclusion operation then a subtotal colectomy can be performed when the patient's general condition is better suited to a major operation.

Case 3.—Man aged 46.

History.—Since the age of 21 he had suffered from severe attacks of asthma. In 1940 he was treated as a case of ulcerative colitis. Since that date he had had recurrent attacks of rectal bleeding with some diarrhœa. Lately he had been worse and his Hb had fallen to 43%.

On examination.—4.2.48: A pale man with no abnormal signs save those of chronic bronchitis. Sigmoidoscopy showed no ulceration but the mucosa was œdematous. A barium enema was normal. He was discharged home.

29.9.48: He was readmitted with increasing anæmia. Bleeding time, clotting time and prothrombin estimations were normal.

Operation.—28.10.48: Laparotomy. The whole colon from cæcum to lower pelvic colon appeared hæmorrhagic; the coats were œdematous but there was no real induration. If rubbed, the surface of the bowel resembled that seen over an active peptic ulcer. The abdomen was closed.

18.12.48: After consultation with the patient an ileostomy was performed.

9.3.49: Removal of the left half of the colon. He recovered well and attended the follow-up clinic; he was readmitted because of persistent bleeding from his mucous fistula.

28.9.49: The remainder of the proximal large bowel was removed. The operation was difficult as the mesentery was loaded with fat and bleeding was excessive.

His recovery was prolonged by the following complications: intra-abdominal abscess, fæcal fistula and *B. coli* bacteriæmia from a thrombophlebitis. Fortunately he survived all these catastrophes and is now home. In the future it may be possible to close his ileostomy by anastomosing it to the stump of his pelvic colon.

Pathological report on the removed colon (Professor Dorothy Russell and Dr. W. W. Woods):
Macroscopical

Resection of lower part of colon 9.3.49 (S.D. 415/49)

The piece of colon is about 20 to 25 cm. long and 3·5 to 4·5 cm. in circumference after some hours in formaldehyde. The mucosa is normally folded and is injected by numerous minute red specks. This redness is now only moderate and in places slight. There are no erosions, ulcers or membranes. There is no obvious thickening of mucosa (0·15 cm. thick), submucosa (0·3 cm.) or muscle (0·25 cm.). Meso-colic glands are very small (largest 0·4 cm. diam.). Three pieces of colon were taken for section.

Resection of cæcum and remainder of colon 29.9.49 (S.D. 3841/49)

The gut is about 78 cm. long and varies in circumference from 7·5 cm. in ascending colon to 4 cm. in splenic flexure, after one hour in formaldehyde. The mucosa in cæcum, ascending colon and hepatic flexure is deep red, in transverse colon paler, but quite pronounced red, and in remainder pinkish-grey. In the cæcum there are a few purplish-red patches and some of them have a very thin, opaque, grey membrane on their surfaces; there are smaller similar areas in ascending colon. The submucosa is swollen (about 0·5 cm. thick) and gelatinous, suggesting œdema. The appendix has numerous red patches on its mucosa. Meso-colic glands must be very small because none were found in the abundant fat.

Pieces taken for sections were two from cæcum and one each from ascending, transverse, splenic flexure and descending colon.

Microscopical

The changes are almost the same throughout all the nine sections taken from different parts of the large intestine removed at the two operations. They indicate diffuse inflammation of an ordinary simple type affecting mucosa and inner part of submucosa.

In the lumina of a moderate number of mucosal glands there are small masses of neutrophil leucocytes (pus), and occasionally red blood corpuscles. There are neutrophil leucocytes between the surface epithelial cells, these leucocytes being on their migration to the lumen of the gut.

In many places the superficial epithelium is absent. Most of this is probably due to post-operative trauma during examination of the specimen. But there are a few minute areas where neutrophil leucocytes have poured through breaches in the epithelium and these areas are therefore probably pathological erosions. There are, however, no well-established ulcers such as one would have expected to be associated with the clinical hæmorrhage.

Very numerous plasma cells are packed closely in the mucosal stroma, obviously in greater number than in normal mucosa. Eosinophil leucocytes are moderately numerous, but are not more than are found in many simple inflammations.

Mucosal capillaries are congested. Red blood corpuscles lie free in many small areas of mucosa, mainly superficial, and in the cæcum there are a few larger superficial hæmorrhages at breaches in mucosa and muscularis mucosæ, with on their surfaces indefinite membrane of red corpuscles, leucocytes, epithelial cells and a little fibrin, but it is difficult to exclude operative trauma as the cause of these.

The blood vessels just outside the muscularis mucosæ are dilated in all sections, and in this plane there is moderate infiltration with plasma cells, lymphocytes and eosinophil leucocytes. Occasionally this infiltration is concentrated around the vessels, but there is neither hyaline degeneration nor necrosis of any vessel.

In a section of descending colon there are in the submucosa two minute groups of giant cells like those of tuberculosis, but these minute groups are not like tuberculous lesions because although they contain lymphocytes, there are hardly any epithelioid cells. There is one similar group in the submucosa of the transverse colon. But these are the only items by which this superficial cæco-colitis differs histologically from other examples of simple inflammation. For instance, the changes are similar to those in ordinary acute catarrhal appendicitis.

The muscularis is normal.

The inflammation of serosa in some sections is obviously the result of previous operations.

I have never encountered a similar case before and was unable to find a similar one in the hospital records. In my opinion this man may have suffered from an allergic manifestation in his colon allied to his asthma. On top of these allergic attacks he had gradually developed a simple colitis which in time might have developed into a true ulcerative colitis. Neither at operation nor in the specimen was there any evidence that he had ever suffered from an ulcerative lesion.

Comment.—The diagnosis of colonic disease is difficult despite the aid of radiography: the diagnosis of ulcerative colitis should never be made in the presence of a normal rectal mucosa.

If surgical treatment is required for any type of colonic infection then multiple stage procedures should be carried out whenever possible; they are far safer and it is quite likely that the second operation may never be required.

Mr. Guy Blackburn quoted a case of regional colitis in a lady of 72, with a very short history and no disease in the small gut. This was analogous to regional ileitis, and it was clear that a process similar to regional ileitis could occur in the large gut without any lesion in the ileum or jejunum. The absence of lymph-node involvement in the large bowel contrasted with the clinical picture of Crohn's disease.

Mr. John Hosford said that he had not had the same happy experience as some other surgeons in excluding a loop of bowel affected by Crohn's disease but had found it necessary to do a second operation to excise the entire lesion.

Film: Perineo-abdominal Excision of the Rectum.—W. B. GABRIEL, M.S., F.R.C.S.

Before showing this film, Mr. Gabriel mentioned a few points as guidance to those who might contemplate having a surgical film made.

(1) As the operation proceeds from stage to stage the various steps have to be indicated either by "cutting" or by "fading". The "cutting" method is, I think, more neat and gives a quick transition readily appreciated by those who are familiar with the technique of the operation which is being demonstrated: whereas the "fading" method gives a blurred image for a second or two and this gives a warning that another step is following. Perhaps the "fading" method has some advantages for those who are not familiar with the operation. In this film both these methods are shown, the "fading" method being evident particularly in the perineal stage.

(2) When a long focus lens is used as it was in parts of this film, especially in order to get a close-up view of the perineal dissection, it must be remembered that the field is quite a small one, probably not more than 12–15 inches in diameter. Time must therefore be given to the film operator to get his camera properly aligned and focused, and if the surgeon wishes to demonstrate any particular point he must be sure that he is within the restricted field that is being filmed.

(3) As regards the use of titles and sub-titles, I think in a silent film such as this if long descriptive sub-titles are used they rather tend to break the continuity and smooth flow of the film. I therefore decided in this film to cut the legends down to the bare minimum, namely a short sub-title before each of the three main stages of the operation (preliminary abdominal exploration, perineal dissection, abdominal mobilization and completion of colostomy), together with an indication of the time usually taken over each stage in a reasonably favourable case.

[The colour film was then shown]

Mr. Gabriel then continued:

The advantages of this method may now be indicated briefly.

The perineal dissection is done early in the operation by accurate dissection.

The pelvis is cleared from below upwards: this is a great advantage when a massive growth has to be mobilized, especially in men with a narrow pelvis.

The rectum and whole of the pelvic colon are removed up to the left iliac colostomy: this is of much importance when related polypi or multiple carcinomas are present.

There is no intraperitoneal division of the bowel.

A steep Trendelenburg tilt is not required and when the peritoneal stitch is begun from below, most cases need no more than 15 degrees tilt head down, or possibly up to 20 degrees

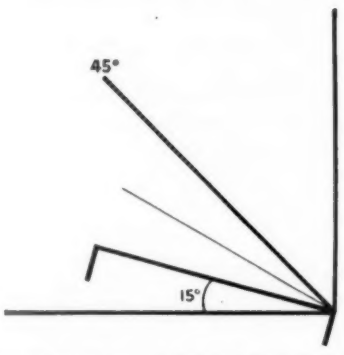

FIG. 1.—Diagram to show 15 degree Trendelenburg tilt, which is usually sufficient for a perineo-abdominal excision and even this is only required for a few minutes.

for a few minutes when closing the pelvic floor (Fig. 1). There is no doubt that a high Trendelenburg tilt imposes a great strain on the heart and respiration of many patients, especially

the short obese type, and predisposes towards post-operative pulmonary collapse. A maximum tilt of no more than 15 degrees is an ideal that can easily be achieved by the perineo-abdominal operation.

As regards anæsthesia, we seem so often to be called upon to deal with patients with extremes of blood pressure, both high and low, that I am now doing a series of perineo-abdominal excisions without spinal anæsthesia. A straight general anæsthetic of pentothal, nitrous oxide-oxygen, cyclopropane or ether is given and at the preliminary laparotomy I infiltrate the abdominal wall with 1% procaine (20 c.c. left and right) and also inject 10 c.c. of 1% procaine into the base of the pelvic mesocolon as the pelvic colon is held out by the assistant. Although under this regime a moderate drop in blood pressure occurs, the general condition of the patients has remained very satisfactory, with a slow pulse, and a very quick post-operative recovery to normal has taken place: of course the usual blood transfusion and glucose-saline drip has been given post-operatively but pressor substances have not been required.

The time taken by this operation is usually one hour and ten or fifteen minutes—less or more—according to the technical difficulties encountered.

The number of cases of carcinoma of the rectum and anal canal treated by this method, from 1932–1949 inclusive, has been 795 with a total mortality of 90=11·3%.

A fair indication of the reduced mortality since the adoption of stainless steel wire for the abdominal wall, with sulphonamide and penicillin therapy when required, is shown in the following table:

TABLE I.—PERINEO-ABDOMINAL EXCISION FOR CARCINOMA OF THE RECTUM AND ANAL CANAL (ONE STAGE)

Recent Operation Mortality

All hospital and nursing-home cases since August 1947.
Out of 151 cases, 7 deaths=4·6%

At St. Mark's Hospital:

1947	33 cases	2 deaths
1948	36 cases	1 death
1949	39 cases	1 death
Total	108 cases	4 deaths=3·7%

I wish in conclusion to express my thanks to Messrs. Kinocrat Film Unit for the time and trouble which they took in making this film.

The German Food Shortage 1946–47 and Effects of Unlimited Food on Undernourished Men

By E. M. WIDDOWSON, D.Sc.

WHEN the Medical Research Council's Unit was established in Wuppertal in June 1946 the official rations provided 1,050 calories a day for the "normal consumer". Very few people lived as "normal consumers", however, because there were so many scales of supplementary rations that most persons managed to qualify for one or other of them. Extra food was also obtained in other ways, the most important of these being what was known as "Hamstering", that is, bartering goods with farmers in exchange for food.

The signs and symptoms of undernutrition in Germany in 1946 were those of a calorie deficiency, but not of the most severe type. The people looked pale, particularly the men, and most of them had lost a considerable amount of weight. The œdema was more common in men than in women, especially in men over 40, and it was usually confined to the legs. It generally disappeared after a few days' rest in bed. We saw no signs of vitamin deficiency, and there were no complaints of diarrhœa. There were, in fact, none of the signs of really severe undernutrition such as were found in the concentration camps.

Towards the end of 1946, an investigation was carried out on the effects of giving unlimited food for eight weeks to 19 undernourished men. Their ages ranged from 26 to 80 years. All but 2 had œdema and all but 1 were underweight. The extra foods they received were bread, potatoes and other vegetables, margarine, cheese, sugar, tinned meat and fish, and dried milk and cocoa. Their average calorie consumption over the whole period was about 6,000 a day, and their average gain in weight during the eight weeks was just over 10 kg. When the experiment ended and they went home, their body-weights fell again until June 1947, and thereafter there was a steady rise.

There was a significant rise in pulse-rate, basal oxygen consumption, serum and blood volume, hæmoglobin and hæmatocrit levels, and serum protein concentration as a result of the unrestricted diet. The blood pressures were low at the outset, and there was no rise during the course of the investigation. All the men suffered from nocturnal polyuria before the investigation began, and there was some improvement at the end of the experiment.

There was no change in the incidence or degree of œdema during the eight weeks of unlimited food, but it almost disappeared over the course of the next two years. The extracellular fluid volume was high at first, and there was a reduction in the absolute volume as well as in the volume expressed as a percentage of body-weight.

It is suggested that an increase in the volume of extracellular fluids is one of the most important changes brought about by undernutrition and that it takes place in all undernourished people, whether they have œdema or not.

Serum Cholinesterases in Undernutrition

By R. A. McCANCE, F.R.S., M.D., F.R.C.P.

SINCE the general level of serum proteins was known to fall in undernutrition, and since the serum enzymes are probably specific proteins, we thought it might be interesting to estimate the activity of these enzymes in the serum of undernourished persons. No change was found in the activity of alkaline phosphatase which could be attributed to undernutrition, but serum cholinesterase was found to be low, and the activity rose as the plane of nutrition improved. It is thought that the level of cholinesterase activity in a person's serum is a reflection of his plane of nutrition, but the normal range is wide. Experiments in Germany showed that an improvement in diet gradually raised the level of cholinesterase activity to normal and that a return to insufficient rations led to a fall. The activity of this enzyme in the serum is not a reflection of the forced metabolism of any of the major dietary constituents, for 200 grammes of protein or fat per day for a week made practically no difference to the level of cholinesterase activity in the serum of undernourished persons. The pseudo-enzyme is more sensitive to the plane of nutrition than the specific enzyme, but both are affected. The activities of these enzymes in dogs or in male rats are not reduced by undernutrition but the activity does fall in the serum of female rats when they are starved.

The Effect of Undernutrition on the Size of the Baby at Birth and on the Ability of the Mother to Lactate

By R. F. A. Dean, M.R.C.S., L.R.C.P.

The Unit of the Medical Research Council formerly working in Wuppertal made abstracts of the records of the local Landesfrauenklinik der Rheinprovinz for the years 1937 to 1948. The analysis of these data showed that, although there was no increase in the incidence of toxæmias of pregnancy, stillbirths or malformations,

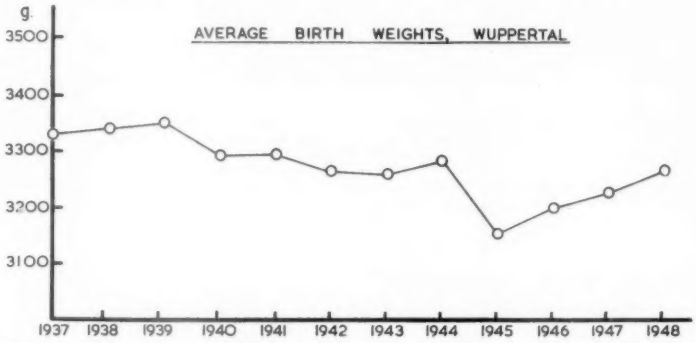

Fig. 1.—Average birth-weights of children born at the Landesfrauenklinik der Rheinprovinz, Wuppertal, 1937 to 1948.

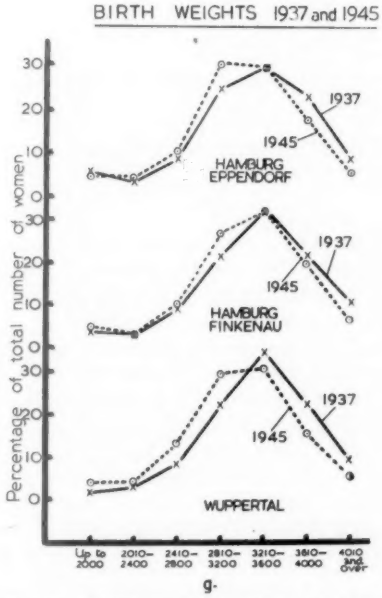

Fig. 2.—Percentage distribution of birth-weights in 1937 and 1945 at the Landesfrauenklinik, Wuppertal, and at two Hamburg hospitals. In each case the curve for 1945 is to the left of that for 1937 indicating that in 1945 more small children were born. The number of children involved in each analysis is between 1,200 and 2,600 and the differences are statistically significant.

there was a sharp fall in the average birth-weights in 1945 when the food situation was at its worst (Fig. 1). The children born then were about 185 grammes lighter than those born in 1937/8, but in the following years the weights rose again. The average length at birth was about 19 mm. less in 1945/6 than in 1937/8. The average period of gestation was shortened by 1·25 days but this would account for reductions of only 45 grammes in weight and 2 mm. in length in a normal child. Weight changes similar to those found in Wuppertal also occurred in Hamburg at the Eppendorfer Klinik and the Frauenklinik Finkenau (Fig. 2).

The ability of the Wuppertal women to breast-feed was greatly reduced in 1945/6 (Fig. 3) and the "physiological" loss of weight of the child after birth continued longer

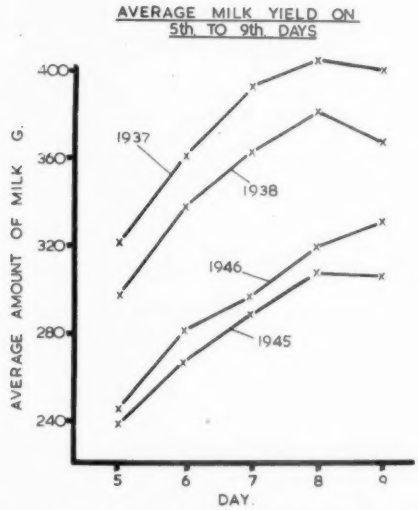

FIG. 3.—Average milk yields on the 5th to 9th days in 1937 and 1938, 1945 and 1946 at the Landesfrauenklinik, Wuppertal. The difference between 1937 and 1945 on the 5th day was nearly 90 grammes and there were similar differences on each of the other days.

than in 1937/8. The gain of weight in the first ten days was also slower, especially in the heavier weight groups. The progress of about 300 children born in 1946 was followed for the first six months and at the end of that time the average amount of weight gained was about 107% of the birth-weight.

The alterations in birth-weight confirmed the similar reports from the Hague, Rome, Stalingrad, Vienna and Erfurt and the fact that even a minor degree of under-nutrition such as that seen in Germany can reduce the size of the child appears now to be established. Lactation has not previously been studied quantitatively but there is no reason to suppose that the Wuppertal figures are unique. The causes of the failure of lactation are obscure. Some experimental work suggests that shortages of calcium in the diets may have played a part. It is also known that lactation is subject to psychological influences, and the mothers were probably adversely affected by the extraordinary difficulties that beset their daily lives.

DISCUSSION ON ANOMALIES OF THE URETER IN CHILDHOOD

Mr. T. Twistington Higgins: The ureter, by and large, provides us with much of the amusement of children's urology and sets us many difficult problems in diagnosis and treatment.

Most of the anomalies which are met with are clearly vagaries of development: others are of doubtful ætiology, and some are certainly acquired.

CLINICAL PICTURE

The clinical picture is usually determined by urinary stasis, infection and deterioration of renal function though individual cases, for one reason or another, may present with other outstanding features, such as pain, hæmaturia or the presence of a lump or even calculi.

All too often the lesions are bilateral.

Clinical features.—(1) Infection—chronic or recurrent. Pyuria. (2) Disordered micturition. Excessive wetting in infancy. "Enuresis". (3) Pain. Often referred to the abdomen. (4) Lump. Hydronephrosis or abdominal cyst. (5) Defective renal function. Stunted growth. Sallow colour.

The normal ureter.—In the child, the *normal* ureter is outwardly identical in structure and function with the ureter of the adult.

Distinctive features in the child.—Yet there are distinctive features in the child's ureter which are of considerable practical importance. *Calibre*: In infants and very young children, the ureter is a tiny tube. In the newborn infant, a 4 F catheter is a full "fit". One can easily appreciate how readily inflammatory œdema can gum up the lumen and so determine persistence of an infection. In such circumstances, the passage of a catheter and distension of the pelvis with dye can be a valuable *therapeutic* as well as *diagnostic* procedure.

Neuromuscular reflex.—This reflex is notoriously sensitive in all the involuntary muscular tubes of the young (cf. pyloric stenosis, cardiospasm, etc.). The ureter is no exception. Spasm is readily induced and appears to be often very intractable. I feel sure this must be a significant factor in some long-standing infections. It *may* be the explanation of some cases of gross megalo-ureter and hydronephrosis. It is noteworthy that a common sequel to a cleared urinary infection is disordered micturition—urgency, frequency, etc.—"enuresis", if you like.

Symptoms of this kind may persist for months or even years, with a perfectly clear urine and no demonstrable structural abnormality. What may be called a "micturition stammer"—due, I believe, to delayed readjustment of this sensitive reflex.

"Neuromuscular reflex" is, of course, a high-sounding term which means little. Dr. M. Bodian has confirmed for me that the ureteral wall is well supplied with nerve fibres, but no ganglion cells. These appear to be massed in the vesical terminal.

EMBRYOLOGY

The main features are, of course, well established for us. The *ureter originates* as a bud from the lower end of the Wolffian duct of the 4–5 mm. stage, the two having at first a communal duct—the *common excretory duct*. This common duct later disappears leaving the two openings separate. With the development of the bladder, ureteric and Wolffian openings become more separated, so coming to occupy their normal positions:

(1) The ureter—trigone.

(2) Wolffian. *Male*—ejaculatory duct—floor of prostatic urethra. *Female*—The duct of Gartner in analogous position.

At the same time as all this is going on *below*, the bud is growing upwards with the metanephros, ultimately branching out to form the calyces and collecting tubules—which

finally link up with the secreting tubules of the kidney. All this is obviously a very intricate piece of development and it is scarcely surprising that it should sometimes miscarry. Such anomalies as reduplication and ectopic openings are sufficiently intelligible.

There is, however, very little precise knowledge about the fashioning of the ureteric tube, the evolution of its muscle, the finishing touches to upper and lower ends, and so on, and these are matters which are of great importance to us clinically. It may well be that the record of our observations may serve to fill in some of the gaps for the embryologist. We appreciate his difficulties. The fœtus he has to work with is even smaller than our babies!

Classification

Congenital.—Congenital anomalies of the ureter have been very completely classified by Meredith Campbell ("Pediatric Urology", 1937, I, 254, New York) and we may conveniently follow his main headings: (1) Anomalies of number. (2) Anomalies of origin and termination. (3) Anomalies of form, calibre and structure.

Anomalies of Number

Total absence of kidney and ureter.—We are only likely to see this in children when the solitary kidney goes wrong. I have met with it twice, for certain. Both these children were girls, of 10 and 12. Each had a huge infected hydronephrosis. The surprising thing was how long each survived with a mere shell of renal tissue—a matter of several years in each case. In neither of these children was there any sign of a second ureteric opening in the bladder.

Various rudimentary cystoscopic appearances are, however, described—dimples and hypoplasia of the trigone and even short blind stumps.

It is easy to be deceived into thinking one is dealing with a single kidney when œdematous cystitis makes identification of the ureteric orifices and retrograde pyelography temporarily impossible.

Reduplication.—This is a common anomaly. It may be *complete* or *incomplete—unilateral* or *bilateral.* And, since the fission virtually always proceeds from above downwards, splitting of the renal pelvis and kidney is associated. In the incomplete type, the ureters fuse at some point above the bladder, usually low down and even in the bladder wall. Our experience is that this incomplete type, with a single communal vesical orifice is the more dangerous. One ureter, more often that draining the lower renal unit, becomes blocked and, together with its associated renal segment, degenerates into a hopeless pus sac.

Where the ureteral fission is *complete* with two separate vesical openings, the prognosis seems to be better. Many of the infections we have seen in such cases have proved controllable, though, of course, not always.

Where two openings are present the lower always drains the upper pelvis, and the two ureters cross in their course. The accepted explanation of this is that the primary ureteric bud to the primary upper half of the metanephros retains its close relation with the Wolffian duct longer and therefore travels caudally with it, thus crossing the second ureter and assuming a lower site in the bladder.

Total extirpation. Dangers of stumps.—In the worst cases, the only satisfactory answer is uretero-nephrectomy—though hemi-uretero-nephrectomy may always be a possibility. Fortunately the renal pelvic segments are usually quite separate and arranged one above the other. They may, however, communicate (I have seen this occasionally) and they are said to be arranged side by side very rarely (I have not met this). These are eventualities which would make heminephrectomy impossible.

[Slides were shown to illustrate various types of reduplication and one of trifurcation.]

Anomalies of Origin and Termination

Ectopic ureter.—We have not seen many instances of this anomaly; I expect we have missed some. Diagnosis is difficult, especially in the male. The ectopic orifice is very commonly the opening of a *reduplicated* ureter, and being the *lower* of the two ureters, it therefore usually communicates with the *upper* renal segment.

The embryological association with the Wolffian duct explains the sites at which the ectopic orifice is most likely to be found; apart from occasional trigonal eccentricity these are: (1) In the male: (*a*) In the bladder wall. (*b*) Prostatic urethra. (*c*) Into the ejaculatory duct, or seminal vesicle. All these are *within the external sphincter.*

Incontinence is therefore not a feature though enuresis may be. Diagnosis is only likely when urinary infection is a complication, and it is therefore rarely made.

(2) In the female: The opening is most often found in the *vestibule* or the vagina, less often in the *urethra.* Incontinence is the rule and leads to diagnosis. It is noteworthy,

however, that in children, incontinence may be incomplete—at any rate, in the early stages. The child may be quite dry at night and when lying down and only wet when up and running about. And on occasion there may be no incontinence ar all.

Diagnosis calls for ingenuity. When the orifice is in the vestibule, there is little difficulty. When in the upper reaches of the vagina, careful observation may reveal a spurt of urine. Injection of indigo-carmine may help. Catheterization and retrograde pyelography are of course confirmatory. [Slides were shown.]

Suppression of the lower ureter with which may be associated a rudimentary renal segment may explain certain obscure retroperitoneal cysts presenting as abdominal or pelvic tumours.

Anomalies of Form, Calibre and Structure

This is the most important group of all, because it is by far the largest, including in fact most of the anomalies met with. Broadly it comprises:

(*a*) Megalo-ureter
(*b*) Hydronephrosis } With or without demonstrable obstruction.

One or two anomalies of form, not associated with dilatation, may be mentioned:

Ureteral aplasia.—By this is meant an underdeveloped ureter, associated with a hypoplastic or absent kidney. The ureteral lumen is small and there may only be a fibrous cord. Catheterization is impossible. A case was described.

Ureteral displacement.—This is rare in children, apart from tumours and obvious renal fusions. It is very rare in ordinary hydronephrosis (cf. adults). When present one expects something unusual.

Megalo-ureter.—"Hydro-ureter", all too often "Pyo-ureter".

I think we must attempt a clear distinction between *Primary* and *Secondary* megalo-ureter. I admit this is not always too easy. Obstruction at the bladder neck or in the urethra—*by reflux* gives us some of the handsomest of megalo-ureters.

But these are *secondary* lesions to which I can give only a passing reference, fascinating and important as they are.

I only wish to emphasize that in any case showing gross ureteral dilatation, especially if this is bilateral, the site of obstruction is most likely to be at the lower level. The *diagnosis of a lesion as being at the uretero-vesical level*, especially in a bilateral case, should only be accepted after the most careful exclusion of the infravesical possibilities.

I confine myself now to those lesions in which the ureter itself is—or at least appears to be—primarily at fault.

In a *primary* megalo-ureter, the search is, of course, for an obstructive lesion in the *uretero-vesical* region. Very often this is demonstrable, but equally often it is not. The fact is that for many of these megalo-ureters we have as yet no really satisfactory explanation.

The cystoscope may show us:

(1) A definite stricture seen as a small or even "pin-point" orifice. I think a pure mucosal stenosis is uncommon; usually the stricture is more extensive, involving at least the intravesical ureter, which means that effective dilatation will require more than a touch with the diathermy electrode.

(2) We may see the ureteric opening as a *large hole*, resembling the entrance to a *railway tunnel*. This is most often a *diverticulum* with a small true ureteral orifice somewhere in its depths. In lucky cases the catheter may find this and pass easily enough. It is just as likely to fail to do so. This is one of the more common anomalies and one feels it must have an embryological explanation. Chwalla offers important evidence on the point and I hope Mr. Williams will enlarge on it later (Chwalla, R. (1927) *Urol. cutan. Rev.*, **31**, 499). In these cases it would seem that there must be some associated local muscular defect, whether of structure or of tone, to account for the readiness with which reflux occurs.

In other cases, which are much more uncommon, the "railway tunnel" orifice is a *genuine patulous opening*, leading into an equally patulous ureter. Often spoken of as the "fœtal" type. Gérard, L. (Thèse, Paris, No. 63, 1908. "Le form de l'uretère chez le foetus et le nouveau-né") deduced from his researches that the "ureteral bud was wide and large up to the fifth month of fœtal life. (Quoted by Irvin, G. E., and Kraus, J. E. (1948) Congenital megalo-ureter and hydro-ureter, *Arch. Path.*, **45**, 752.)

(3) We may see a *ureterocele*. This is not a common finding in children. It may be that it is a later development. It is often associated with a duplication. It has been known to prolapse through the urethra in girls and a double one may completely fill the bladder. With luck, the ureteral orifice may be seen somewhere on the circumference. It must be considered an obstructive lesion and treated as such. I do not think that simple diathermy is enough. Excision with real dilatation has given us satisfactory results.

(4) *Lastly and perhaps most commonly of all.*

The ureteric opening looks perfectly normal, the catheter passes with ease, and there is, in fact, no obvious abnormality. In this type the lower ½ to 1 inch of the ureter above

the bladder also appears perfectly normal both macroscopically and microscopically. Yet there is a gross dilatation above.

What is the explanation of these cases? Are they congenital or acquired? The analogy to the Hirschsprung colon is remarkable. (Incidentally megalo-ureter is not commonly associated with Hirschsprung as is so often stated. In all our recto-sigmoidectomies, we have inspected the ureters carefully, and only once seen any sign of dilatation. It may of course develop later in life from prolonged pressure of the huge colon.)

Treatment

(1) *Conservative treatment.*—If stricture of the orifice has been definitely diagnosed then it must be dilated.

For a *pin-point mucosal stenosis*, diathermy will, of course, suffice, but, as I have said, this is rare.

True stricture, whether it be congenital or spasmodic, demands something more. Instrumental dilatation through a cystoscope has its very distinct limitations in childhood, and is, at present, only appropriate in selected cases.

To be certain of really efficient dilatation one must usually open either bladder or ureter or both and use bougies and so on. On the whole I think the *ureter* operations have served us best.

In that group with what one must call *achalasia* effective dilatation seems to be of some real value.

The analogy of this type to Hirschsprung's disorder of the rectosigmoid has, of course, suggested to us the possibility of a "pull through" operation. But this has not yet been attempted by us on a living subject. It may prove useful one day.

For the *ureterocele* we have excised the whole ureterocele, suturing the edges after bougie dilatation. The procedure seems to have worked well but I am sure the operation must be a radical one.

One or two other practical points. Where the ureter is tortuous and redundant, it is obvious that even if we relieve any obstruction below successfully, drainage may well be still deficient. Adhesions form between the loops, and stagnant pools persist. Ureters of this type must, I think, be straightened out and even shortened by excision of a segment.

I always fight shy of *reimplantation* myself, feeling that however "dud" the existing ureterovesical junction may be, it is probably better than any I should manage to make.

Finally a greatly dilated ureter should, I am sure, be drained to give it a reasonable chance to recover its tone.

(2) *Radical.*—When extirpation is done it should be *total*. Any sizeable ureteral stump may remain a source of infection and secondary removal can be a difficult operation.

Finally one must say a word about lesions at the *upper* end of the ureter.

Like megalo-ureter, hydronephrosis may be: *Primary* or *Secondary*.

Secondary hydronephrosis will eventually ensue from any ureteral dilatation provided it is sufficiently prolonged. In the young child, the pelvi-ureteric "sphincter" mechanism does "buffer" the kidney for some time surprisingly well. It is an ally to be made the most of.

Primary hydronephrosis is fortunately often unilateral and the determining causes—strictures, kinks and bands, whether or not associated with aberrant vessels, high insertion of ureter into pelvis or in rare cases, apparently "achalasia"—are all more easily understood because they can be exposed and inspected.

In the child we are perhaps more often fortunate to get on to hydronephrosis early, while there is still a kidney worth saving. (If only it were more generally recognized that a child's abdominal pain is not necessarily always in the abdomen!)

We have at any rate carried out conservative procedures of one sort or another in some 40 or 50 cases now, and the results are very gratifying.

Mr. R. K. Debenham showed lantern slides of three cases. The first case was a little girl aged 3 who presented with recurrent attacks of right-sided pyelitis. Excretion pyelography showed a double renal pelvis on the right side, with a double ureter which joined its fellow above the bladder. Cystoscopy showed a normal bladder and ureteric orifices. There was some hold-up in the excretion from the upper of the two right renal pelves, so a hemi-nephrectomy was performed with removal of the upper of the two pelves and most of the corresponding ureter. A subsequent pyelogram showed that the remaining half of the kidney was functioning well. For excretion pyelography in small children Dr. R. Astley, Radiologist at the Children's Hospital, Birmingham, was using hyalase mixed with 12% diodone, given subcutaneously into the buttock in a 30 c.c. dose and the results were most gratifying.

The second case was a girl aged 4½, who presented as a case of nocturnal enuresis but the mother's history was quite definite; she said "this child is always wet". Investigations

showed an ectopic ureter on the right side which opened into the urethra distal to the sphincter; the corresponding kidney was hydronephrotic. The left kidney and ureter were normal. Nephrectomy was performed and the child has been dry since.

The third case was that of a girl aged 10, who also presented as a case of enuresis but on careful questioning it was apparent that the child was always damp and the mother thought she "leaked" after passing water, though she micturated in the ordinary way. Intravenous pyelography showed that she had a double renal pelvis on the right side associated with a single ureter opening in the normal position in the bladder. On the left side, however, there was a double renal pelvis and a complete double ureter. The lower of the two pelves opened by a normal ureter into the bladder and cystoscopy showed no abnormality. The upper of the two renal pelves drained into a second ureter which opened into the urethra almost at the vulva. Owing to stenosis near the lower end of this aberrant ureter a retrograde pyelogram was impossible; there was hydro-ureter and hydronephrosis of the affected pelvis. A left heminephrectomy was performed and the child has been dry since.

Mr. R. A. Mogg showed films of a boy aged 9 who presented a rather unusual anomaly, namely a unilateral double ureter with one of the ureters opening ectopically at the bladder neck as a ureterocele. The boy had had a right-sided pyelocystitis since the age of 3 and had been investigated previously at various hospitals with inconclusive results. He was first seen by the speaker at the age of 6. Apart from the fact that he had had these recurrent attacks of pyelocystitis he was otherwise a normal child. An intravenous pyelogram showed an interesting state of affairs. There was a right renal outline, but there was no secretion from this side. On the left side there was a grossly dilated ureter, the dilatation being greater at the lower end, and there appeared to be a stricture of the lower end of the left ureter. It was difficult to obtain a true cystoscopic appearance of the bladder, but cystoscopy did show a large cyst-like structure occupying the whole of the trigone and preventing further examination of the rest of the bladder; it was then decided to explore the bladder. On opening the bladder it was seen that the whole of the trigone was occupied by a large submucous cyst-like structure which was in fact the dilated ectopic ureter of the right side which was opening as a ureterocele at the urethral orifice. The dilatation was so great that it was causing a definite obstruction of the left ureteric orifice and also of the normal right ureteric orifice. The ureterocele was resected and the trigonal mucosa was sutured and a new ureteric orifice was made below the existing one on the right side. The bladder was drained suprapubically. Convalescence was uneventful and since operation there have been no further attacks of pyelocystitis. Intravenous pyelogram now shows a poor secreting right kidney with a normal secreting left kidney, but the dilatation at the lower end of the ureter on that side still persists. Retrograde catheterization of the three ureteric orifices, namely, the left and the two right ureteric orifices, was quite easy. There was no evidence of any obstruction of an organic nature to any of these ureteric orifices. Specimens of urine have been obtained from the right ureteric orifices on three occasions and they have all been sterile on culture giving no evidence of any active infective process in the right kidney. The interesting thing in this case was that there were two conditions present, a complete double ureter on one side with one of the ureters opening ectopically at the bladder neck as a ureterocele and associated with what appeared to be a stricture or spasm of the ureter on the other side. It had been suggested that the so-called stricture on the left side might have been due to adhesions between the lower end of the ureter and the vas giving rise to the peculiar pyelographic changes. The fact that this ureter could be catheterized very easily would rule out the possibility of an intrinsic pathological process being responsible for the so-called stricture.

Mr. D. Innes Williams said it was to be regretted that in connexion with these cases of congenital megalo-ureter more was not known about the fœtal ureter. It was generally agreed among embryologists that by the fourth or fifth month of pregnancy the fœtal ureter was comparatively wide, straight, and of uniform calibre, but that after that dilatations and deformations occurred, with narrowing at the pelvi-ureteric junction, the pelvic brim and where the ureter passed through the bladder muscle. It was not clear why the dilatation appeared. Although the experimental evidence was rather confusing it did not seem very likely that the urinary secretion was adequate to "blow out" the ureter. Possibly the reason was that the ureter was at first growing more rapidly in comparison with the rest of the fœtus, and later in pregnancy it grew more slowly, and this was borne out by studies of pathological dilatations in dead fœtuses. If there was persistence of the fœtal ureter of this latter type there would be a hydro-ureter with an intramural part of normal calibre. In order to get the wide gaping orifice it seemed as if there must be some defect at a very much earlier stage, and a defect in the form of the bladder muscle, not of the ureter or ureteric muscle. Chwalla (1927, *Urol. cutan. Rev.*, **31**, 499) had described the formation of a membrane from the time that the ureter departed from the Wolffian duct, and had suggested that this membrane was responsible for ureterocele, and, moreover,

that its partial delay and eventual disappearance were responsible for congenital diverticula at the site of the orifice. He showed an illustration from an early paper indicating the urogenital sinus with the ureters opening into it, and the terminal dilatation of the ureter. This was at a very early stage when the musculature of the bladder had not yet formed. It had been suggested that if the membrane persisted for a little it might lead to the persistence of the terminal dilatations, which would then present, in post-natal life, as pouches at the site of the orifices. Several of these cases had, in fact, pouches into which the ureter opened, and in such cases the ureter above was very widely dilated indeed and allowed free reflux.

Mr. Innes Williams suggested that in these cases of megalo-ureter with gaping orifices this defect in the bladder muscle was the primary defect, and that the strong contractions of the inflamed bladder had, in the absence of the uretero-vesical valve, blown up the upper part of the ureter. Perhaps that was the only defect, though there might, of course, be some defect in the ureter also. It did suggest that if the ureter could be kept clean and sterile these cases would not progress and there would be no evidence of renal failure.

Mr. H. P. Winsbury-White said that there was one type of dilatation about which he wished to speak, and that was the mild dilatation which so often presented a practical problem in hospital and elsewhere. This was seen, of course, in cases of infection, and the academic point arose as to which came first, the dilatation or the infection. It was known that dilatation was a constant accompaniment of infection in a mild degree. The problem could not be solved on the spur of the moment. The infection was dealt with for the time being by medication, but it tended to recur as intermittent pyelitis and cystitis. The bladder should be investigated to make certain whether there was or was not any residual urine there. The dilatation of the ureter might be expected to continue, if the residual urine in the bladder could not be made to disappear.

There was another point about the dilated ureter. As far as stone in the upper urinary tract in children was concerned dilatation was a most important ætiological factor. Many of the cases discussed that evening also had residual urine in the bladder, and that added to the difficulty of treatment. He had occasionally brought about a temporary improvement in the child's condition by doing a suprapubic cystotomy, and in other cases he had resected the bladder neck. This was not an easy thing to do in a child. The approach to the internal urinary meatus through the bladder was very narrow and he had never succeeded where there was a large amount of residual urine in getting rid of such urine completely, although it had been possible to reduce it considerably.

Mr. David Band showed a number of lantern slides and discussed the differentiation of megalo-ureter due to uretero-vesical achalasia, from hydro-ureter associated with achalasia of the bladder neck. In the former the bladder emptied properly, and, there being no demonstrable stricture of the urethra or bladder neck, it must be assumed that there was a failure to relax at the uretero-vesical meatus. The pathology of achalasia was not understood, and he thought they should beware of adopting a rationalistic outlook which was the privilege of physicians and surgeons up to two hundred years ago, but which was a danger to those who practised medicine and surgery to-day.

He proceeded to show a number of urograms of cases of achalasia of the bladder neck. The first was from a young man who had reported for medical examination for the army. It was found that he had albuminuria. There was incomplete emptying of the bladder and the cystogram showed a grossly distended bladder with reflux up grossly dilated ureters. The blood urea was over 100 mg.%. At this stage he did a presacral neurectomy, and drained the bladder suprapubically. Eighteen months later the blood urea still remained as high as 80 mg.%, but the patient was remarkably well. A transurethral resection of the bladder neck was performed, and subsequently micturition returned to normal, and voiding was complete. The blood urea had since then fallen to 30 mg.%, but there was still regurgitation to the upper urinary tract. The patient was now in full employment as a miner.

The second case was that of a young soldier who also was found to have albuminuria. He had an over-distended bladder, but without regurgitation, as shown in a cystogram. There was again no apparent contracture of the bladder neck. After transurethral resection complete emptying of the bladder was restored. Microscopic examination of the resected bladder muscle revealed no abnormality of the muscle fibres or stroma, and no nervous elements.

The third example was a case of achalasia of the bladder neck in a little girl, and here again restoration of complete evacuation of the bladder contents and improvement of renal function was brought about by resection of the bladder neck.

In a series of cases of megalo-ureter due to achalasia presacral neurectomy had been carried out without any appreciable alteration in size for several years. Yet in the case

of a girl of 18 years who had severe infection of the right kidney and gross megalo-ureter on the right side, there was on the left side a lesser degree of achalasia with a typical "snake's head" ureter. A right nephro-ureterectomy was carried out and later the lower end of the left ureter was excised and a reimplantation of the ureter to the bladder was done. This girl two years after the reimplantation had remained well. A pyelogram of the result of the reimplantation showed that the ureter remained of normal size and the renal function was excellent, as demonstrated by intravenous pyelography and the ordinary function tests.

A boy at the age of 10 years, had infection of the urinary tract and was found to have a megalo-ureter of lesser extent on the right side and a gross megalo-ureter on the left. Presacral neurectomy was carried out, and function remained good seven years later, but without appreciable alteration in the size of the ureters. A similar case was one of bilateral megalo-ureter subjected to neurectomy with the same result. The last case was that of a boy aged 1 year in whom the cystogram showed an obstruction in the posterior urethra with gross dilatation of the ureters, and who had a congenital obstruction in the prostatic urethra. The case had been seen by Mr. Twistington Higgins, who had dealt successfully with the obstruction. Subsequently, Mr. Mason Brown resected the lower 4 inches of the ureter and carried out a reimplantation of the ureter to the bladder. He was glad to say that at the age of 3 years this boy was still very well. His baby brother, however, at the age of 4 months became very ill. There was a distended bladder. The ureters showed a marked degree of dilatation, and retrograde pyelography revealed a bilateral hydronephrosis. Symptoms of uræmia developed and bilateral nephrostomy was done. This was an extraordinary example of two brothers with exactly the same congenital malformation.

Mr. Band added that he could not believe that sympathectomy was necessarily the treatment of choice in cases of achalasia. If the urine was kept sterile very possibly the upper urinary tract would remain remarkably well without surgical intervention. In those cases in which a satisfactory renal function gave some expectation of reasonable chances of survival, excision of the recalcitrant segment of muscle offered possibilities. In megalo-ureter resection of the lower segment of the ureter and neo-uretero-cystotomy had given satisfactory results, and he was convinced that resection of the bladder neck was the treatment of choice in cases of urethro-vesical achalasia.

Mr. E. W. Riches said that he was stimulated to intervene in the discussion owing to Mr. Band's reference to sympathectomy. He himself was not a protagonist for sympathectomy. He agreed that until they knew more about the ætiology of megalo-ureter they did not know how to treat it. Apart from Mr. Williams' most valuable contribution, they had not heard much in that discussion about ætiology. They had seen Mr. Higgins's enormous collection and realized how difficult the problem could be for those who had regularly to treat children with these conditions.

He believed that the first case of sympathectomy for this condition was done in 1933 by Ogier Ward. That was a success, but later cases had not been so successful. He was sure that with such dilated ureters as they had seen that evening they would never have a complete success from sympathectomy because there was too much fibrosis in the ureter to allow it to resume its normal size.

He had had referred to him by Professor Alan Moncrieff a girl aged 4 who had recurrent *B. coli* infection. She had been treated for more than a year by medical means including sulphonamides, but always relapsed. Pyelography showed that there was a certain amount of dilatation of the ureters though never very gross. Having read Ogier Ward's paper, he carried out a pre-sacral sympathectomy on that child. From the picture five years later the ureters appeared normal, but the striking thing was that she ceased completely from that day to have her recurrent attacks of infection, and he was sure that in this case pre-sacral sympathectomy did good. She had a little sister born subsequently to her own operation, who had exactly the same history of recurrent attacks of *B. coli* infection. The condition in this second case was more marked on the right side than on the left, but both ureters were dilated. They waited until the child reached the age of 4, and then did a pre-sacral sympathectomy. The result as seen two years later showed that the regression had not been as marked as in the case of her sister, but the lower ureter was less dilated, and infective attacks had ceased. When the ureter was very large it was quite obvious that nothing like presacral sympathectomy was going to do any good, and he had not hesitated to reimplant the ureter into the bladder. The intravenous pyelogram showed a diminution of size after operation.

He felt, as he had already said, that they did not know much about the ætiology in these cases, but if they had only one case of this sort which did respond to sympathectomy they must seriously consider a neurological source of the dysfunction as the initiating cause, at any rate in some cases. But where there was a gross obstruction it must be relieved, and the bladder neck could be resected in some cases. It was in those cases in which no obstruction at all could be found that the difficulty arose. He hoped that if others got these cases at an early stage they would not feel that presacral sympathectomy was entirely to be avoided.

WARD, R. OGIER (1933) *St. Bart's Hosp. Rep.*, **71**, 17.

The President reported the case of a child, first seen in 1928, with bilateral megalo-ureter. There was intense cystitis which was treated by the best means at their disposal in those days. He showed a slide illustrating the cystoscopic findings at the lower end of the ureter at the end of treatment. Here there was a sheet of mucous membrane which bore some resemblance to a ureterocele except that the central opening was large. A photograph showed the patient by the side of a normal youngster of the same age, revealing that the child was an excellent example of renal dwarfism. He thought that the retardation of growth was probable in these cases, and was rather surprised that none of the earlier speakers had mentioned it. He lost sight of the boy until 1943, when, a grown man, he turned up in good health except for a complaint of persistent pain on the right side. The right kidney and ureter proved to be diseased and were removed. The left kidney and ureter were then quite healthy, although twenty years previously they had shown characteristic dilatation throughout. It appeared, therefore, in 1928, the importance of the disease was grossly exaggerated by superimposed infection and it appeared further that control of the infection had led to a degree of improvement which no one would have anticipated.

Mr. Twistington Higgins, in replying to the discussion, said that several interesting questions had been raised, notably in regard to the ureteral dilatations without obvious obstruction as seen in infants and less often in older children. Further work on the ætiology of these was essential. He stressed the adaptability of growth and the wisdom of non-interference, as far as possible, in infancy. He thanked Mr. Winsbury-White for calling attention to the minor cases of dilatation, and agreed that these were very troublesome and the infection persistent. This type probably fell into the group of spasm, undue irritability of the neuromuscular mechanism about which so little is really known. It was a type which could be controlled more readily with modern drugs. A better understanding of the neuro-muscular mechanism might well solve many problems in childhood, apart from those in the urinary tract.

It was perfectly true that the stone was commonly only an incident in an obstructive lesion, and the underlying cause must be dealt with. Removal of the stone alone was not enough.

On the question of residual urine, they had learned that many perfectly normal children had a certain amount of residual urine, up to quite an appreciable quantity (2–2½ oz.).

Resection of the bladder neck had been done in a number of his cases after careful selection, with considerable benefit. Children, otherwise unable to empty the bladder, had been able to acquire the facility of normal expression.

Sympathectomy had been mentioned by Mr. Band and Mr. Riches. He was not impressed by the results of either spinal anæsthesia or sympathectomy. He felt that more satisfactory help was available now in the form of drugs like pituitrin and more simple measures.

Mr. Twistington Higgins then thanked his colleagues at the hospital, its nursing staff whose patience and skill with these children was beyond praise, his devoted young assistants, who were such a valuable stimulus, and Mr. Derek Martin for invaluable help with the illustrations.

DISCUSSION ON THE MEDICAL TREATMENT OF AURAL VERTIGO

The Medical Treatment of Ménière's Disease

By J. KODICEK, L. R. S. TAYLOR and G. H. BATEMAN

(*St. Thomas's Hospital, London*)

Mr. G. H. Bateman: The work on which this contribution is based has been done at St. Thomas's Hospital and Mr. L. R. S. Taylor and Mr. J. Kodicek have been largely responsible for it. Mr. Taylor will give details of the cases treated and the results obtained in our series.

There are two conceptions of Ménière's disease, firstly that it is a primary affection of the vestibular apparatus and, secondly, that it is a vestibular manifestation of a constitutional disorder. We think that most would agree that the second hypothesis is correct and this opinion is supported by the various medical treatments that have been discussed and tried in the past few years, e.g. Mygind and Dederding's restriction of fluid intake and salt-free diet, treatment with urea to aid excretion of sodium, and also by Wright's focal sepsis and the Scandinavian intestinal intoxication theories. Incidentally we may be wrong in ascribing this latter to Scandinavia as it has been the basis of the spa treatment of Ménière's disease, and other diseases, for a long time. Histamine therapy is based on a vasoconstriction theory of the causation of the disease and it appears that Miles Atkinson's theory grew out of this. It is very difficult to trace the origin of the various theories as they soon get distorted. Miles Atkinson's latest paper read at the Fourth International Congress in London in July 1949 emphasizes vitamins, and histamine is mentioned only as a convenient method of differentiating between the various vitamin-B deficiencies.

Results of treatment are very diverse, but the varied habits of living and perhaps climate of many countries may provide different causes of labyrinthine pathology, and therefore the results of treatment found in one country cannot always be comparable with those in another.

On analysing the results of the treatment we have followed at St. Thomas's Hospital we feel that, while not curing all patients of their symptoms, we have succeeded in providing them with a *modus vivendi*, free from the fear of sudden crippling attacks of giddiness.

This treatment is our interpretation of one advocated by Miles Atkinson in 1946 in a paper read to this Section at Torquay (*Proc. R. Soc. Med.*, **39**, 807). His theory was that the vertigo is caused by a vascular disorder of the small vessels of the labyrinth resulting in excessive formation of endolymph. This disorder may be primary vasodilatation with excessive transudation supposedly through the stria vascularis of the scala media, or a primary vasoconstriction of the arterioles which leads to an anoxia of the capillaries and this in turn leads to excessive transudation through the capillaries when the vasoconstriction passes off. This may be likened to Raynaud's disease. The two groups may be distinguished by a histamine skin test. 0·05 c.c. of a 1 : 10,000 solution of histamine (0·275 mg. of histamine diphosphate in 1 c.c.) is injected intradermally in the flexor aspect of the forearm 2 in. below the bend of the elbow. The result is read fifteen minutes after the injection. A negative reaction is a central circular wheal of about ¼ to ½ in. in diameter surrounded by an areola of 1½ to 2 in. in diameter. A positive reaction gives an irregular central wheal of 1 to 1½ in. in diameter with centripetal pseudopodia and a bigger areola round it of 2 to 3 in. in diameter. There are some intermediate results which should be retested with a double dose of histamine and those which are not definitely positive should be considered negative. There are difficulties in interpretation of this test and errors of classification become obvious in failure of response to treatment. When wrongly classified cases are often made worse by therapy and improved when the other treatment is substituted.

Negative cases are treated by vasodilatation; this controls the vasoconstriction and so prevents the anoxia which causes the increased permeability of the capillaries. Nicotinic acid is the vasodilator we have used and big doses must be given. 100 mg. t.i.d. is a moderate dose and doses up to 250 mg. t.i.d. have been necessary to relieve the symptoms in some cases. Intramuscular injections of 35 or 50 mg. of nicotinic acid are sometimes needed in the early stages. If the symptoms are controlled, dosage must be continued indefinitely though it can often be reduced.

Positive cases are treated by histamine desensitization. 0·05 c.c. of a 1 : 10,000 solution of histamine is first injected subcutaneously and the treatment is continued by repeating the injections on alternate days, increasing the dose by one-half on each occasion. The dose is taken up to about 0·4 c.c. of a 1 : 1,000 solution. It is rarely possible to take up the dosage at this rate throughout the course and if the reaction, flushing, palpitation and headache, is severe, the previous dose should be repeated and the rate of increase reduced. A course thus lasts about four weeks.

Miles Atkinson now advocates the use of enormous doses of riboflavin for positive cases, such as 90 mg. t.i.d. but the price is prohibitive in this country.

Mr. L. R. S. Taylor: Cases have been selected which fulfil the criteria laid down as constituting Ménière's disease: perceptive deafness, tinnitus and vertigo occurring in bouts. Headache or head pains have been found in nearly every case, and these have often been previously diagnosed as migrainous and have been centred on the ear.

Caloric reactions were tested after the method of Cawthorne, Fitzgerald and Hallpike, using water at 44° C. and 30° C., delivered for 40 seconds from a suspended douche can. Time was taken from the start of stimulation until nystagmus ceased as estimated by the observer using reflected light, and confirmed where possible by the patient. Fifteen minutes were allowed between each test, the whole test taking over an hour to complete.

Cases were divided into positives and negatives by an intradermal skin test made by injection of histamine two inches below the bend of the elbow in the centre of the flexor aspect of the forearm. The reason for this choice of injection site is to facilitate readings in doubtful cases and to aid in standardization. The grouping is dependent on the anatomy of the lymphatic system and therefore, for comparison, the same site must be chosen in each patient. Results are read fifteen minutes after injection. Straightforward cases have already been described. The doubtful cases show small serrations or even centrifugal pseudopodia, but these must be ignored. Any pseudopodium extending upwards, if associated with a good erythema and bleb, should be read as positive. If the injection is made subcutaneously the result will always be negative, hence the necessity for accurate placing of the needle.

Unfortunately the easiest way of learning to read these tests is the hard way of experience, which may be uncomfortable to the patient and disheartening to the physician. The results obtained have, however, justified the time spent.

The treatment of the negative group will be considered first. The patient is told to take 100 mg. of nicotinic acid three times a day before meals, and to expect a warm flush in the face, neck and forearms ten minutes later, lasting for about ten minutes. If no flushing occurs the patient is told to chew up the tablets before swallowing.

After a week the patient is seen again and, if nothing untoward has occurred, 100 mg. t.d.s. a.c., are given for a month before he is seen again. In severe cases intramuscular injections of 50 mg. or 100 mg. once or twice weekly, or even daily at first, have been given. A few cases were bedridden when first seen. These were admitted to hospital and treated with larger doses; injections of 75 mg. intramuscularly were given to one man three times a week at first. It is exceedingly important to stress the necessity of the continuation of a small maintenance dose when the symptoms are controlled. This will vary from patient to patient, but we have found 100 mg. t.d.s. to be an adequate dosage, although individuals often require a greater amount. This is a continuous treatment and makes no pretence of curing the underlying cause of the disease. The natural history is one of irregular bouts of attacks. These must still be expected by the physician and patient and, at the first warning sign, for example increase in tinnitus, an intramuscular dose is given of 50 to 100 mg. and an extra 100 mg. daily should be taken by mouth for a few days. In women, we have found an intramuscular injection of 50 mg. forty-eight hours before the expected menstrual period to be very effective in warding off an attack. Thorne and his co-workers have shown that in women there is a considerable sodium retention in the immediate premenstrual period with consequent cerebral œdema. Any tendency towards labyrinthine hydrops will therefore be accentuated at this time. The onset of acute coryza is another indication for increasing the dosage temporarily.

The histamine positives present a simpler group clinically for treatment, though in our hands results have not been so satisfactory as for the negatives. This is contrary to Atkinson's experience. Cases after completion of histamine desensitization have remained well for varying periods up to eighteen months, but all have required a second course, and it would seem that a maintenance dosage fortnightly or monthly is necessary.

The dangers associated with this form of therapy are few. Excess nicotinic acid is said to cause imbalance in vitamin B complex absorption. Two cases on very high daily dosage (800 to 1,000 mg. daily) have indeed shown such symptoms (emotional instability, feeling of fullness of head and photophobia) and both have been relieved of their complaints within a week by reducing their doses. A third case exhibited nausea, vomiting and water brash signifying a severe gastritis and a fourth constant diarrhœa, until the nicotinic acid was rested on the former, and dose reduced in the latter. These symptoms should be controlled by giving a compound vitamin B capsule.

Subcutaneous injection of histamine if given slowly will be without reaction, but if given too deeply into the muscles, or intravenously, produces alarming temporary symptoms of histamine shock (correctable by adrenaline (1 : 1,000 solution) minims v. intramuscularly, or intravenously) and in elderly hypertensives would not be without danger.

A total of 53 patients has been treated by the Miles Atkinson method. In none of these was there any doubt as to the diagnosis. All the patients attended a special clinic and were supervised by the same team of clinicians throughout. Caloric vestibular reactions have been studied in 37. The remaining 16 cases had no caloric tests for various reasons.

Age and sex distribution.—Of the 53 patients 23 were men and 30 women. The ages varied between 21 and 75, but practically half the patients were between 40 and 60 years of age.

TABLE I.—AGE AND SEX DISTRIBUTION (53 PATIENTS)

Age in years	20–29	30–39	40–49	50–59	60–69	70–79
Male ..	—	8	4	6	5	—
Female ..	1	4	7	9	7	2

Histamine skin reaction.—15 patients were "positive" (28%). This figure is rather higher than Atkinson's. 11 of these were females and 4 males. No special age incidence was noticed. The remaining 38 patients were histamine "negative" (72%) and both sexes were equally represented.

A number of errors in the histamine grouping were made early in the series, mainly through incorrect reading of the reaction and through subcutaneous injection of histamine. A marked increase in the severity of symptoms was noted in these cases, sometimes with remarkable suddenness. Repetition of the test and the institution of appropriate treatment resulted in rapid improvement and none showed any permanent ill-effects (e.g. increased deafness).

Effect of treatment.—Vertigo responded extremely well, being relieved in 32 (60%) cases and improved in another 20 (38%).

Tinnitus.—Relief was obtained in 12 (23%) and improvement in another 22 (42%). In the latter group the musical component was usually lost, leaving the pulsatile (vascular) tinnitus.

Deafness.—Both subjective and objective improvement in hearing was noted in 10 cases (19 %), the average gain in the speech range being about 10 decibels.

Headaches were noted as a marked feature in 25 cases (47%). Relief was obtained in 17 of these and improvement in duration and severity in a further 6 cases.

TABLE II.—RESULTS OF TREATMENT

	Vertigo	Tinnitus	Deafness	Headache
Relieved ..	32	12	—	17
Improved ..	20	22	10	6
No change ..	1	19	43	2

The cases have been followed up for a period of 18-30 months. The number of favourable results far exceeded that resulting from any other non-operative treatment we have tried. Furthermore the inconveniences to the patients of special dieting and restriction of water intake are avoided, while at the same time they are allowed to return to an active and useful life.

Mr. I. A. M. Macleod, *General Hospital, Nottingham.*—In June 1946 there was a group of 7 patients attending the Aural Department of the General Hospital, Nottingham, suffering from such severe symptoms of Ménière's disease that they were completely incapacitated. They had undergone practically all the recognized courses of medical treatment, and in three instances surgical measures had also been carried out. Unable to work, their symptoms unrelieved, they had abandoned all hope of being able to live useful lives again. Following the Address given to this Section that summer by Dr. Miles Atkinson [1], it was decided to try his methods of treatment on this group. The results of the decision, which was virtually one of despair, were so encouraging that in order to study the method more thoroughly it was extended to further cases and has now become a routine in the Department.

The series analysed here is of the first 50 consecutive cases. More cases have occurred but they are either still undergoing treatment or the time elapsing since the cessation of therapy has been too short for purposes of review. 28 cases have been male and 22 female. All have been unilateral in type and have exhibited the triad of acute vertigo, tinnitus and deafness in varying degrees of severity. It is interesting to note that 26 of the patients have been wakened from sleep by the onset of vertigo—some on more than one occasion.

Treatment has been carried out according to the results obtained from the histamine skin test described by Atkinson [2]. The salt used for skin testing and therapy has been histamine acid phosphate. This has been prepared in the research laboratory of a large drug firm in Nottingham who produce ampoules of a sterile 1 : 10,000 solution calculated in terms of histamine base, and I should like to acknowledge our gratitude to Sir Jack Drummond for his great help in this connexion.

In the interpretation of the skin test at the beginning of the series two independent judgments of the results were exercised lest one observer might be erroneous in his conclusions. Using normal saline, and in some cases horse serum, as a control in the "untested" arm

and counting no reaction as sensitive, unless one or more "pseudopodia" developed, it soon became evident that reactions were clear-cut and definite and gave rise to no uncertainty. Viewing the reaction by oblique light gave greater relief to the edges of the wheal and pseudopodia. Further, by using an intradermal injection of 0·1 c.c. of a 1 : 10,000 solution of histamine base, instead of 0·1 c.c. of a 1 : 20,000, it was found that wheals and pseudopodia in sensitive cases became more sharply defined, but not larger or longer than when the weaker solution was employed. Similarly, in insensitive cases the edges of the wheals were more raised and sharp, but there was no tendency to develop pseudopodia, nor was the reaction time prolonged.

Of the series, 32 cases gave an initial sensitive reaction, 14 were insensitive, and the remaining 4 were intermediate, i.e. the wheals were approximate to a positive reaction in size and duration but presented a scalloped or budded periphery without the formation of true pseudopodia. I do not think there is any significance in this initial large number of sensitive cases, as the proportion of sensitive to insensitive and intermediate reactions is tending to even out, the larger the series grows.

The sensitive group.—The cases in this group were treated by weekly subcutaneous injections of histamine. The initial dose was 0·1 c.c. of a 1 : 10,000 solution of histamine base. This was increased by 0·1 c.c. weekly, working up to a concentration of 1 : 1,000 solution of histamine base until a reaction was shown by the patient in the form of flushing and headache following the injection. This dose was repeated or increased thereafter on three occasions so that four consecutive reactions were produced. Treatment was then discontinued. This reaction point varied from 0·3 c.c. of the 1 : 10,000 solution to 0·4 c.c. of 1 : 1,000 solution, but so far no patient has required a greater dose than 0·5 c.c. of a 1 : 1,000 solution of histamine base.

On the average most patients felt better by the time they had recieved 0·3 c.c. of 1 : 10,000 solution, in that their attacks of vertigo had decreased in number, intensity and duration, and in some cases the vertigo had ceased altogether. A striking point was the sense of well-being and return of confidence they exhibited.

Regarding the results of therapy to date, I am aware of the shortness of the time factor involved, but without trying to offer any definite conclusions I think that so far they appear to be encouraging.

Of the 32 histamine-sensitive cases 23 have remained free from vertigo since the end of their course of therapy, the time factor being a minimum of six months and a maximum of two years and eleven months. Six cases have relapsed and had further attacks of vertigo, 3 of these after six months' freedom 1 after nine months, and two after one year. 3 of these cases on retesting had become histamine-insensitive and responded to nicotinic acid after histamine made their symptoms worse. The other 3 were still sensitive and responded to further histamine therapy. All have now remained free for periods of over six months.

Three cases have not shown improvement in that they are still subject to attacks of vertigo at intervals of less than two months.

The histamine-insensitive group.—This group has been treated by nicotinic acid. Initially intramuscular injections of 25 mg. to 30 mg. were given daily combined with oral administration of 50 mg. to 200 mg. The balance between individual tolerance and freedom from symptoms has varied greatly, but most patients have been stabilized on oral dosage only, ranging from 50 mg. to 400 mg. daily.

Of the 14 cases thus treated 9 have remained free from vertigo. 4 cases relapsed; 2 of these responded to increased dosage and 2 became worse. According to the skin reaction, these 2 cases had become histamine-sensitive and were relieved of their vertigo by a course of histamine injections.

One case has not improved though apparently remaining in the histamine-insensitive group.

The intermediate group.—In this group of 4 cases 2 have remained symptom free on nicotinic acid therapy and 2 have been unrelieved.

SUMMARY OF RESULTS

Group	Histamine sensitive	Histamine insensitive	Intermediate	Total	%
Vertigo-free ..	23	9	2	34	68
Relapsed ..	6	4	0	10	20
Unimproved ..	3	1	2	6	12

Freedom from vertigo, with its accompanying nausea and vomiting, has been taken as the criterion of improvement in this series. It has been found, however, that improvement in tinnitus and deafness did not take place nearly so frequently.

In 11 cases tinnitus disappeared completely, whilst in a further 9 cases it became less intense though still present. In 30 cases it was unimproved.

Improvement in hearing has been least frequent and only 9 cases have shown an appreciable increase in the hearing level, as checked by audiometry before and after treatment; 41 cases being unaffected.

	No. abolished	%	No. improved	%	No. unaffected	%
Tinnitus	11	22	9	18	30	60
Deafness	Nil	0	9	18	41	82

2 —— (1946) *J. Laryng. Otol.*, **61**, 344.

Mr. C. S. Hallpike said he was glad to hear Mr. Bateman use the term Ménière's *disease* of the labyrinth. In his view the use of the term Ménière's *disease* was justified and represented a clarification of their ideas on the fundamentals of the disorder.

Ménière's disease was in some ways a very satisfactory condition to treat, but in other ways less so. In the majority of cases satisfactory results could be obtained with judicious sedation with luminal, and nothing else. This meant that anyone who knew this and was capable of diagnosing the condition could treat it with success, and it was in fact so treated by neurologists, general practitioners and others. But when they came to the group of patients who did not do well on this very easy treatment, special chemical methods had to be employed, and again, in his experience, a high proportion did well.

Here the unsatisfying feature was that the patients seemed to do well whichever of these special treatments was selected, and here arose the difficult question of their rationale. If they reverted to the early history of this subject, in particular histamine therapy, they had been told that histamine sensitivity as shown by skin tests meant that the patient was suffering from a labyrinthine manifestation of histamine of which he could be relieved if his resistance to histamine were increased by means of histamine injections. From the point of view of theoretical immunology that had always seemed an unsound notion. Sometimes an allergic basis for Ménière's disease had been suggested, but the manifestations of allergy were multiple, while, on the whole, other allergic phenomena were not seen in Ménière's disease. Further, allergic patients always had their first allergic manifestations early in life, whereas in Ménière's disease the symptoms appeared later. Finally, in allergy there was nearly always a family history of the condition, which was not seen in Ménière's disease.

As regards skin tests, they had been told that if the patients were sensitive to histamine on skin tests, histamine should be given in such cases, but if they were insensitive, they must have nicotinic acid. But the experience of himself and his colleagues at Queen Square did not seem to bear that out (Harrison, M. E. S., 1945, *St. Thomas's Hosp. Gaz.*, **43**, 88). If subjects were negative to histamine with skin tests, this did not seem to forbid successful treatment with histamine, and *vice versa*. Histamine and nicotinic acid were chemically quite different, but they had this in common that they probably produced an increase of the circulatory rate in the labyrinth. It did not seem to matter very much which was given.

In the cases in which he had been concerned, histamine or nicotinic acid was used in accordance with this principle, not much notice being taken of skin tests, and the dose was regulated to produce the maximum circulatory effect. He hoped that further work would be done on the circulation of the fluids in the internal ear, since until more was known of this he did not think there could be any sound basis for either the treatment or the prognosis of this disorder.

Mr. H. V. Forster said that about the year 1910, as a junior physiologist he had been interested in a certain type of intermittent inner ear deafness, characterized by low tone loss, though exacerbations might occur with a sensation of fullness in the ear, clonus of one or other of the intratympanic muscles, and a sense of disorientation, aggravated by movement of the head. It was not until the publication of S. H. Mygind's researches that he felt that a reasonable explanation of these cases of bass inner ear deafness had been offered

The development of successful medical treatment for morbus Ménière, quite apart from the relief of the symptom of vertigo, might preserve the function of the cochlea if such cases of deafness were recognized in the early stages. He had been informed by an American colleague that "dramamine" the now well-known seasickness remedy, was useful in Ménière's disease. He understood that this preparation was a theophyllinate of benadryl and the formula of the Canadian preparation "gravol" had been given to him as follows: Beta-dimethyl-amino-ethyl-benzohydryl ether: 8-chlorotheophyllinate.

He had consulted the medical superintendent of one of the great liner companies, and understood that theophyllin compounds of the anti-histamine drugs available in this country were being tried out for seasickness, with hopeful results from phenergan theophyllinate. He, Mr. Forster, had recently attempted the treatment of a few cases of tinnitus from a small supply of "dramamine". He would be very interested to hear from members of the Section of any experience they might have in the use of these newer modifications of the anti-histamine drugs in morbus Ménière.

Mr. I. Simson Hall said that a similar investigation had been in progress in Edinburgh and he was, therefore, well acquainted with the painstaking and time-consuming character of the work which had been described by the openers.

Mr. Hallpike had already referred to the difficulties in ascertaining the rationale of treatment. He himself had been interested in this subject for a good many years, and on looking through some of the older cases he found that he had tried each routine as it was brought to his notice and that in the case of the salt-free diet system and again in the early histamine treatment, each claimed approximately the same proportion of success. Now there had been added to this the nicotinic acid therapy and a higher percentage of success was reached. Certainly in the series of cases observed in Edinburgh, the observations extending to one year or more, the success as measured in the relief of the vertigo approached 83%. This was for 40 cases.

The difficulty was to assess the value of each treatment as it was introduced. A much greater time would be required before the success of any of these newer treatments could be judged. In an attempt to assess the progress which had been made he had examined the records regarding the references to operative treatment. It seemed to him that instead of accepting the fact that a patient had been free from attack for two years it would be well to see how many cases had been complete failures. Out of a series of 150 to 200 cases he discovered that 20% had been referred for surgical treatment—in other words, they were complete failures. In the last series of cases, from 1946 to a year ago, 15% were complete failures in the sense that they had been referred for operation. In this respect he thought a definite advance in the treatment of Ménière's disease could be claimed for the new methods.

Mr. E. J. Gilroy Glass said that from his own observations he could say that results with Miles Atkinson's treatment had been better than anything he had seen before. He had been particularly struck by the sense of well-being and confidence of the patient.

There were two cases in Mr. Macleod's series which he had not mentioned. They were very alarming at the time though very suggestive in retrospect. Owing to an error in dispensing a batch of histamine, it was made up to 1 : 10 instead of 1 : 10,000, or, in other words, 0·79 gramme instead of 1 mg. Two patients received this injection. Both dropped completely unconscious, with very severe shock, and one was thought to have expired. They both recovered, however, and the interesting thing was that neither of those patients had had any vertigo since. An even more significant thing was that both those patients, who had been extremely deaf, had normal hearing when they recovered consciousness. In one case the normal hearing was maintained for six months and in the other for one month. It was not an experiment to be repeated, but something happened with the histamine which restored the hearing, at least temporarily.

Mr. Terence Cawthorne desired to associate himself with what Mr. Hallpike had said. He was interested in Mr. Simson Hall's figures, because, in their own series of cases, he had found that whatever medical treatment was advised about 50% seemed to be benefited. If one carried on from one medical treatment to another a further 25% came into the satisfactory group—the group, that is to say, in which the attacks were perhaps not cured but were kept at bay. There remained the 25% for which surgical treatment might be required.

There was one aspect of Ménière's disease or hydrops of the labyrinth which deserved consideration. It was sometimes forgotten that this was a disease of the cochlea as well as the vestibule, and he had been struck by the variation of the hearing in these cases of of fluctuating hydrops of the labyrinth. One day the hearing was down, particularly in the low tones, and on another day it was up. One could measure the progress not only by the symptom of vertigo but actually by the change in the hearing which was often easily demonstrable with the audiogram.

From what they had already heard it was quite clear that in many cases medical treatment would give moderately good results, but when it came to the rationale underlying these forms of treatment it was very difficult to be precise or convincing. From time to time further theories might be brought forward; he was quite sure they had by no means got to the end of the story. The advent of dramamine and other histamine products had been mentioned. He had had the opportunity of trying dramamine and another product, phenergan, but it was much too early yet to give the results as he had been using these compounds only for the past three months. In some cases they might produce useful results, while in others the patients said that the cure was almost worse than the disease.

Dr. M. G. Good, speaking from the point of view of a physician, said that he found many a patient suffering from vertigo which was not dependent on an ear condition. The cause was an "idiopathic myalgia", a functional disease of the skeletal muscles. An article on this subject was published in the *Lancet* (1940 (ii), 326) claiming that idiopathic myalgia may simulate visceral, neurological (neuralgia, neuritis) diseases and also vertigo. This "muscular vertigo" is often associated with headache localized by the patient in the occiput—occipital headache. The characteristic "myalgic spots" are regularly found and can be objectively located in one or both trapezius muscles. On appropriate injection of 1–2 ml. of procaine into each myalgic area the complaints disappear very rapidly and permanently.

The concept developed by the speakers that Ménière's disease arises from a disturbance of circulation in the labyrinth appealed to him as a basis of further research. It might, in his opinion, be due either to vasoconstriction—diminished inflow—or vasodilatation, leading to stagnation of the blood and diminished outflow. The common denominator is diminished blood flow, i.e. quantity of blood passing through the unit of tissue per minute, which of necessity leads to a relatively diminished oxygen supply or hypoxia. The relative oxygen deficiency may cause noises by irritation or interference in hearing by hypofunction of the acoustic nerve fibres: it is known that nerves and brain have the highest oxygen consumption.

Dr. Good suggested that the concept of disturbed circulation could be tested experimentally: if nitrites, femergin or other vasodilators produced a relief, even of a temporary nature, the complaints were likely to be caused by vasoconstriction. On the other hand if some of the patients were improved by ephedrine, methedrine, the therapeutic effect would certainly favour the assumption of vasodilatation as the basis of the disease. The discussion had clearly shown that two types of Ménière could be distinguished. It appeared possible to the speaker that the distinction was due to vasoconstriction or dilatation respectively.

Mr. Bateman, in reply, said he did not altogether agree with Mr. Hallpike that most of these patients could be relieved by sedation. Some could be relieved in that way, but he did not think that sedation would put many cases into the "satisfactory" group though it might be that a number would go into the group labelled "improved". As for allergy, he thought they would get into great complications if they started discussing that subject. He did not think, however, that allergy entered into the ætiology of this disease in any appreciable number of cases, but he disagreed with Mr. Hallpike when he said that it did not matter if one failed to differentiate the two groups, positive and negative to the histamine skin test. If therapy were started without carrying out the histamine test one could predict with great accuracy what the histamine test would have shown.

He had seen one or two cases who had been given dramamine for their Ménière's disease. This therapy seemed to come into the same category as sedation. It would produce more relief than most sedatives but it would not produce complete relief such as could often be brought about over a long period with the treatment described in the opening papers. He should have stressed a little more the feeling of well-being of these patients; it was quite remarkable how they would comment on their feeling that they could now do things which they did not attempt before. In other words, they had lost their nervousness and they were able to go back to work and to enjoy it in very many cases.

Observations on the Pathological Mechanism of Conductive Deafness in Certain Cases of Neuroma of the VIII Nerve

By M. R. Dix and C. S. Hallpike

*From the Otological Research Unit, Medical Research Council, National Hospital, Queen Square, London, W.C.*1

Until recently it has been our impression that the tuning-fork tests in cases of unilateral deafness due to VIII nerve neuroma conform to the classical pattern of so-called "nerve deafness". That is to say, the sound of the fork with Weber's test is typically referred to the normal ear, Rinne's test is positive, and perception with the absolute bone conduction test is reduced. Should the Rinne be negative it is a false negative; that is to say, the apparently good perception by bone conduction with the affected ear is due to the transfer of the vibrations to the opposite cochlea, through which it is in fact perceived. This well-known fallacy is recognizable and can be excluded by abolishing the perception by the normal ear of this bone-conducted sound by means of an air-conducted masking sound.

In the course of a previous communication made to this Section (*Proc. R. Soc. Med.*, 1949, **42**, 527), we said that there were some exceptions to this rule, in which a true negative Rinne appeared to be present in the ear affected by the neurofibroma and it is this point to which we return to-day.

So far as we know, all writers who have published their observations upon the tuning fork tests in the deafness of VIII nerve neuroma are in agreement that they conform to the classical pattern of nerve deafness and they have little more to say on the subject. All observers except one, T. H. Just, who in an excellent paper published in 1930 (*Proc. R. Soc. Med.*, **23,** 722) insisted that in certain cases of VIII nerve neuroma the negative Rinne is no artefact, but a true and, as he described it, "disturbing phenomenon".

In our own experience at Queen Square we have encountered a number of cases of this kind. In 2 of these death followed surgical intervention carried out soon after our examination and we were able, through the good offices of Dr. Greenfield, to carry out a histological examination of the temporal bones.

It is the purpose of this communication to describe our findings, and explain how we think they account for this interesting, and as Just described it "disturbing" anomaly—the negative Rinne—in the tuning-fork test results.

The first of our subjects was a man of 57, and the second a woman of 47. They were under the care of our colleagues at Queen Square, Drs. Walshe and Carmichael, to whom we are greatly indebted for permission to investigate the cases and to make use of the clinical notes. The findings in both were characteristeric of an VIII nerve neuroma.

Case I.—A. E., male, aged 57, under the care of Dr. F. M. R. Walshe.

Complaint: Pain behind the left ear and deafness, left ear, four years. Numbness left side of face and unsteadiness in walking, seven months. He had recently experienced difficulty in winking his left eye, and in tasting things on the left side of his tongue.

The pain behind the left ear had been intermittent, never very severe, and never lasted for more than a few hours at a time. The deafness had never been accompanied by tinnitus and in the patient's opinion was quite slight. The difficulty in walking was constant but not severe. He tended to run into things on his left side and was unable to turn round quickly without losing balance. He had never actually fallen or needed support, and there had never been any giddiness.

Neurological findings.—General condition: alert and co-operative.

Visual fields full, fundi normal. Pupils normal. External ocular movements full. Corneal reflexes: right brisk, left absent.

Diminished sensation to cotton-wool, pin-prick and cold over the whole distribution of the left V nerve, including the tongue and hard palate. Some weakness of the left temporal muscle. Slight weakness of the left side of the face of the lower motor neurone type, with impairment of taste over the anterior two-thirds of the tongue on the left. IX, X, XI and XII cranial nerves normal.

Motor system: Normal except for very slight inco-ordination with the heel/knee test on left side.

Neurological diagnosis (Dr. F. M. R. Walshe).—Left VIII nerve neuroma.

X-rays: Normal skull. No evidence of enlargement of the internal auditory meatuses. Ventriculography: Slight, symmetrical hydrocephalus. The aqueduct was lengthened and bowed slightly backwards. The fourth ventricle was displaced to the left, and the anterior border rotated to the right. *Conclusion.*—A left cerebello-pontine angle expanding process (Dr. J. W. D. Bull).

C.S.F. lumbar puncture: Pressure 160 mm. Cells: White nil. Red 5 per c.mm. Protein 260 mg. per 100 c.c.

Otolaryngological examination.—Hypo-æsthesia to pin-prick on left side of soft palate, left side of tongue and left inferior turbinate. Tympanic membranes normal. Other findings normal.

Cochlear function.—Whisper (normal 30 ft.): Left, at meatus. Right > 20 ft. Weber (512 c.p.s.) referred to left. Rinne, Left: Negative with masking of right ear. (The masking procedure was carried out by means of a speaking tube through which an assistant applied to the right ear a continuous sh-sh-ing sound.)

Pure tone audiometry (air conduction only).—With the left ear there was an approximately uniform loss (50 db.) for all tones up to 2,048 c.p.s. Above this frequency the loss increased and 8,192 cycles could not be heard at the maximum output of the audiometer (90 db.). There was also a slight loss of hearing in the right ear (Fig. 1A).

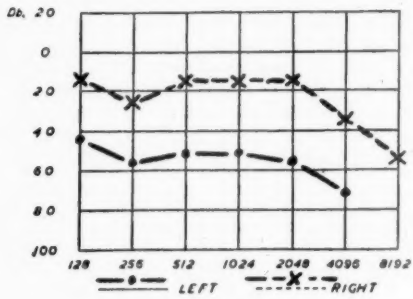

FIG. 1A.—Case I.

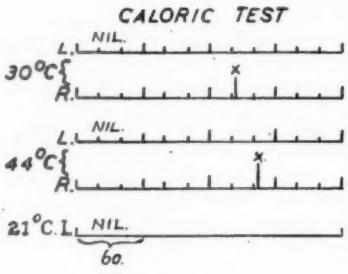

FIG. 1B.—Case I.

Vestibular function.—Posture and gait: A marked tendency to drift to the left when standing or walking with the eyes closed.

Spontaneous nystagmus: With the head erect, first degree vestibular nystagmus was present both to the left and to the right, that to the left being of greater amplitude than that to the right.

Positional nystagmus: In the supine position with the head back and to the left second-degree positional nystagmus of the central type was present to the right. Optokinetic nystagmus: This was markedly diminished to the left, particularly at higher speeds of the drum.

Caloric responses: Complete abolition of the left responses with some directional preponderance to the right of the right responses (Fig. 1B).

Summary of otological findings.—Cochlear function: Partial deafness of the left ear; conductive type. *Vestibular function*: Spontaneous nystagmus. Positional nystagmus of the central type and abnormality of optokinetic nystagmus. Complete loss of the left caloric responses.

Otological diagnosis.—Left VIII nerve neuroma.

Operation.—The left cerebello-pontine angle was explored on 28.10.46 by Mr. Wylie McKissock. The left cerebellar hemisphere was lifted and retracted medially to reveal a small typical acoustic neuroma lying in the cerebello-pontine angle. A complete extracapsular removal was carried out.

Following the operation the patient recovered partial consciousness but became drowsy two hours later and died in coma on the following day.

Post-mortem.—The tumour cavity lay between the upper and lower halves of the cerebellum and indented the left side of the pons in its lower half. The tumour had been completely removed. Histological examination showed it to be a neurofibroma of rather unusual histology. Examination of the pons showed almost complete hæmorrhagic destruction of the tegmentum passing inwards as far as the mid-line against the ependymal lining and extending backwards along a line running from the central fovea of the ventricle to the outermost part of the ventral surface.

The temporal bones were removed and on superficial examination appeared normal apart from a moderate degree of enlargement of the left internal auditory meatus.

CASE II.—G. B., female, aged 47. Under the care of Dr. E. A. Carmichael.

Complaint.—Deafness in the right ear three years. Suboccipital headaches six months. Attacks of vomiting with nausea three months.

The deafness was of gradual onset. Recently it had become progressively worse and had been accompanied by "a noise like a railway engine" all over the head. For a short time before admission she had been rather unsteady with a tendency to deviate to the right. No history of giddiness, although objects sometimes tended to "sway up and down".

Neurological findings.—Alert and well orientated in space and time. No impairment of memory. Visual fields full. Mr. Williamson-Noble reports: "Slight blurring of both discs but within physiological limits." Pupils normal. External ocular movements full. Corneal reflexes: Left present, right absent. Loss of sensation to pin-prick and cotton-wool over the facial distribution of all three divisions of the right V nerve but no motor weakness. Slight weakness of the right side of the face of the lower motor neurone type, and slight fibrillation of the right side of the tongue with deviation to the right. Motor system: Upper limbs—some loss of tone and inco-ordination of the right hand and right leg. Loss of sensation to pin-prick over the second cervical segment. Reflexes: Rt. K.J. > left K.J.

X-rays (including Towne's projection): Normal skull. Ventriculography: The fourth ventricle was dilated and displaced upwards and to the left, the displacement being most marked at its lower end. The appearances were those of a space-occupying lesion in the posterior fossa on the right side.

Neurological diagnosis.—? Right VIII nerve neuroma. C.S.F.: Pressure 80 mm. clear and colourless. Cells: 1 lymphocyte per c.mm. Protein 300 mg. per 100 c.c.

Otolaryngological examination.—Tongue, palate, pharynx and larynx normal. Nose and naso-pharynx normal. Tympanic membranes: Left—imperforate, marked atrophic changes. Right—imperforate, slight atrophic changes.

Cochlear function: Whisper (normal 30 ft.). Left: > 20 ft. Right: At the meatus. Weber (512 c.p.s.) referred to left. Rinne: Left positive. Right negative, with masking of the left ear. (Masking as in Case I.) Absolute bone conduction: Right slightly reduced.

Pure tone audiometry (air conduction only). Left normal. Right: There was a severe loss chiefly affecting hearing for the highest and lowest frequencies (Fig. 2A).

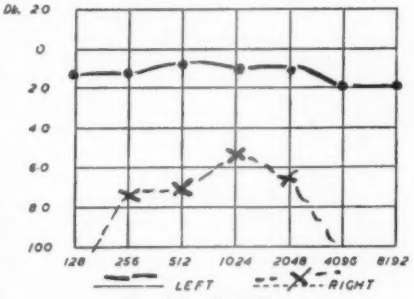

FIG. 2A.—Case II.

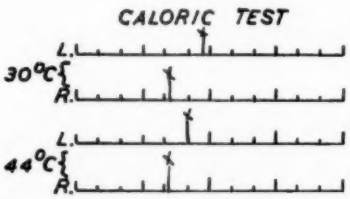

FIG. 2B.—Case II.

Vestibular function: Spontaneous nystagmus: With the head erect, first-degree vestibular nystagmus was present both to left and right, that to the right being slower than that to the left. Positional nystagmus: In the supine position, second degree positional nystagmus to the left was present with the head back and to the right. Optokinetic nystagmus: The response to the left was abolished. Caloric responses: A well-marked diminution of the right responses to both cold and hot stimulation. No directional preponderance was present (Fig. 2B).

Summary of otological findings.—Cochlear function: Partial deafness of the right ear. The deafness was, in some respects, characteristic of a conductive lesion.

Vestibular function: Spontaneous nystagmus, positional nystagmus and abnormality of optokinetic nystagmus. Reduction of the right caloric responses.

Otological diagnosis.—Right VIII nerve neuroma.

Operation.—The right cerebello-pontine angle was explored on 7.3.46 by Mr. Wylie McKissock. On retraction of the right cerebellar hemisphere a typical and fairly soft acoustic neuroma was exposed. The surface was coagulated and a considerable amount of tissue removed with the aid of a scoop and suction. Extracapsular removal was then completed.

The patient died on the following day. At post-mortem, hæmorrhagic changes were found in the right side of the pons with flattening of the right middle cerebellar peduncle. A small nodule of tumour remained in the right internal auditory meatus which was not enlarged. Histological examination of the tumour removed revealed a typical acoustic neurofibroma. The temporal bones were removed and on superficial examination appeared normal.

PATHOLOGICAL EXAMINATION OF TEMPORAL BONES

The temporal bones of both subjects were fixed in 10% formalin and embedded in celloidin. Serial sections were then cut in the usual way.

In the course of this procedure it is normally possible to see a great deal of the finer labyrinthine structures through the clear medium of the celloidin. With the affected temporal

bones of these two subjects, however, the labyrinthine structures were obscured by a fine "coagulum" or gel formation which was evenly distributed throughout and completely filled all the perilymph and endolymph spaces. It was much less dense than that found in labyrinthitis and much more even in its texture and distribution than the exudation which commonly occurs in this condition and indeed in any pathological condition of the labyrinth that we have previously examined. The nature of the abnormality is illustrated in Figs. 3 and 4. These are photographs of two celloidin blocks taken during the course of section cutting. Fig. 3 shows a normal temporal bone in which the normal cavities and membranes of the labyrinth can be clearly seen. Fig. 4 shows the affected temporal bone of a patient with an VIII nerve neuroma in which the naked-eye appearances closely resembled those seen in the 2 cases which form the subject of this paper. The obscuration of the membranes and labyrinth spaces is very evident.

When the sections had been cut and stained in the usual way, with hæmatoxylin and eosin, we were further interested to observe that no sign of the "coagulum" so evident during the process of section cutting could be observed. The histological features of the two cases are shown in Figs. 5 and 6. In both, the external auditory meatuses and the middle ears are normal. The internal auditory meatuses are distorted and occupied by the remains of the neuromata. In the cochleæ, higher magnifications reveal degenerative changes in the nerve fibres and cells of the spiral ganglia. In neither of the sections shown, however, is it possible to appreciate that all the labyrinthine cavities are completely occupied by the homogeneous "coagulum" to which reference has been made. The appearance of the sections was next studied without staining and with dark ground illumination. Under these conditions the presence of the "coagulum" could be readily seen. Figs. 7 and 8 are photomicrographs of unstained sections serially consecutive with those shown in Figs. 5 and 6. They are photographed at the same magnification and with dark-ground illumination. In both, the fine "coagulum" can be seen uniformly filling every part of the labyrinthine spaces. The abnormality of this appearance is illustrated by comparison with Fig. 9 which shows the appearance of a normal labyrinth prepared and photographed under identical condition.

Discussion

It is well known that the labyrinthine spaces are the site of a variety of exudates and transudates, resulting not only from VIII nerve tumours but from many other pathological conditions. Nearly always, however, the distribution and texture of the resulting "coagula", if this term be permissible, are much more irregular than that revealed in the present 2 cases. In addition, it is usually demonstrable quite readily with hæmatoxylin stain. It is justifiable, therefore, to regard the present findings as quite unusual and our next task is to consider how they could be applied to the explanation of the equally unusual but clinically important finding of deafness of the so-called conductive type.

The physical problems concerned with hearing by air and bone conduction, though complex, still seem capable of explanation, in their essentials, in terms which can have changed very little since the days of Bezold. It is known, for instance, that in hearing by air conduction by far the greater proportion of the sound energy reaches the basilar membrane by way of the conducting mechanism which includes not only the tympanic membrane and ossicles but also the fluid contents of the labyrinth. In the case of hearing by bone conduction, while a proportion of the sound energy still reaches the basilar membrane by way of the conducting mechanism, other and more direct pathways through the bony cochlear walls are available.

It follows, therefore, that lesions which disturb the conducting mechanism will have their chief effect on hearing by air conduction; hearing by bone conduction will be affected to a smaller extent. In this way we have the poor hearing by air conduction and the relatively good hearing by bone conduction which are typical of conductive deafness and underlie its characteristic tuning-fork reactions, in particular the negative Rinne. The mechanical characteristics of the middle-ear mechanism are, of course, bound up with its function of overcoming, by virtue of its impedance-matching properties, the severe attenuation which normally occurs when airborne sound enters a fluid medium. The efficiency of this function, however, is necessarily dependent upon normal physical conditions of the labyrinthine fluid, and we think it likely in this connexion that the abnormal histological appearances of this fluid described in our 2 cases connote the existence during life, if not of an actual coagulum, at any rate of some considerable change of its density. The suggestion is therefore made that this density change brings about in turn a mechanical change in this, the terminal component of the conductive mechanism, which disturbs its performance as a whole in a manner which is essentially comparable to that brought about by better-known lesions of its other components, as, for example, middle-ear disease or otosclerosis. As

a result, the consequent deafness is of the same conductive type. Loss of hearing by air conduction is severe, hearing by bone conduction relatively good and the Rinne test negative.

If this suggestion be acceptable, then it follows that a conductive element would also be likely to occur in the deafness which results from other forms of labyrinthine disease which are characterized by similar changes in the labyrinthine fluid. Of these, neuro-labyrinthitis, in particular that secondary to meningitis, may be taken as a likely example. In the majority of such subjects the deafness, which is due in large part to the destruction of the nervous elements, is extreme both by air and bone conduction, and no qualitative tests are therefore possible. We have, however, encountered some cases of this kind with partial deafness in whom the tuning-fork tests could be carried out with reasonable accuracy, and in a few of these we have been interested to note the presence of a true negative Rinne. A summary of the clinical features of three such cases is appended.

P. I., aged 10.

History.—Meningitis aged 3. Deafness in left ear noticed at age of 8.

Examination.—Tympanic membranes normal. Rinne (512 c.p.s.): Left negative with masking of right; right positive. Absolute bone conduction (left) much reduced with masking of right.

Audiograms.—(Tests of left ear carried out with masking of right ear, *see below*, Figs. 10A, 10B.)

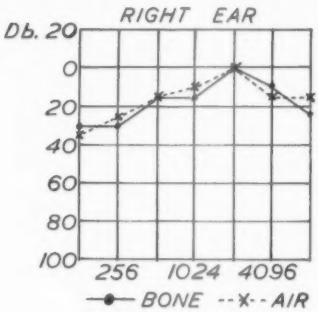

FIG. 10A.

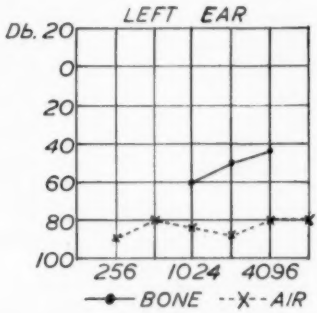

FIG. 10B.

A. P., aged 32.

History.—Deaf since meningitis aged 2.

Examination.—Tympanic membranes normal. Rinne (512 c.p.s.): Left negative; right false negative. Absolute bone conduction (left) much reduced. (*See* Fig. 11.)

R. T., aged 8.

History.—Maternal rubella at second month. Deafness noticed at age of 5.

Examination.—Tympanic membranes normal. Rinne (512 c.p.s.): Left negative; right negative. Absolute bone conduction grossly reduced left and right. (*See* Fig. 12.)

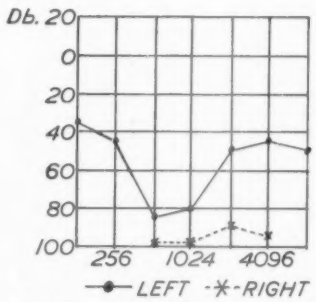

FIG. 11.—Audiogram of Case A. P. (Air conduction.)

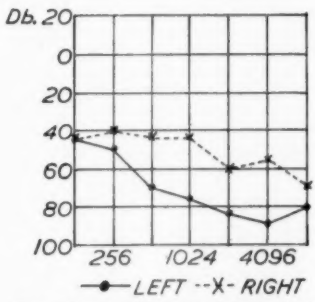

FIG. 12.—Audiogram of Case R. T. (Air conduction.)

A clinical feature of all 3 cases, and one of importance in clarifying the diagnosis, was the reduction of perception with the absolute bone conduction test, a finding to which we attach clinical importance in the diagnosis of disease of the cochlear nervous elements. In 2 of the 3 cases also (P. I. and A. P.) a gross abnormality of the caloric responses was also present. In the third case (R. T.) the caloric tests were not carried out. It seems, therefore

necessary to stress the clinical value in these difficult cases, both of the absolute bone conduction and the caloric tests, since they make so plain that co-existent with the conductive element of the deafness a perceptive element is also present.

In conclusion, it may be said that although the conception of the labyrinthine fluid as constituting an element of the conductive mechanism is not a new one, this would appear to be the first occasion on which it has been possible to give it the support of direct anatomical and clinical observations.

Mr. F. C. Ormerod recalled a discussion on acoustic nerve tumours by this Section in 1923 when the negative results of the Rinne test were mentioned but not discussed at any length. In 1929, T. H. Just definitely described the true negative Rinne and in 1934 Albert Gray described the histology of the temporal bones of two cases of bilateral acusticus nerve tumours (*Proc. R. Soc. Med.*, **27**, 1179). Both patients, one under the care of the late Professor de Kleijn and the other under the care of the speaker, showed a negative Rinne test. In both cases Gray demonstrated otosclerotic changes in the neighbourhood of the oval window and he felt that this explained the negative Rinne. He felt also that the occurrence of otosclerotic changes following acusticus tumours confirmed his theory as to the vasomotor origin of otosclerosis. The findings were illustrated in the second volume of Gray's Atlas of Otology.

Mr. T. A. Clarke asked Mr. Hallpike how the coagulum found in cases of VIII nerve tumour with apparent negative Rinne differed from that found in similar cases with the usual finding of a positive Rinne. It was agreed that perfect masking of the good ear had still to be achieved in testing bone conduction on the diseased side. Could any failure in masking account for the apparent negative response described in the Rinne test in these cases?

Mr. I. Simson Hall said that Mr. Hallpike's findings had interested him enormously. On one occasion during the fenestration operation, in a case of fairly extreme deafness, he opened the labyrinth and found a condition he could not understand. The bone surrounding the canal was rather soft and the outlines were blurred completely. He supposed that the patient must have had a labyrinithitis, but it now occurred to him that Mr. Hallpike's explanation might have been the correct one. The operation was a complete failure.

Mr. Philip Scott said that he was stimulated, on getting notice of this Paper, to refer to some of his notes, and now he was stimulated again to go back and look at his sections. In the sections at which he had had an opportunity of looking he was dissatisfied in one particular case with the negative Rinne. That case did have a noticeable coagulum throughout the section. He now intended to re-examine the section in the light of the observations of Mr. Hallpike and of some others.

Mr. Hallpike, in reply, said that when they began to encounter these cases with evidence of conductive deafness they used to think of the likelihood of an associated otosclerosis, but as they had the opportunity of examining further material they never found otosclerosis, and in the cases shown that day the stapes footplates and middle ears were normal.

Mr. Clarke had asked how this particular coagulum compared with the coagulum which occurred not uncommonly in other conditions of the labyrinth. Generally speaking, such coagulum was much more scattered and less homogeneous than that found in the 2 cases under discussion. As to guaranteeing the efficiency of masking, this it was difficult to do.

He had been very much interested in what Mr. Simson Hall had told them, because in some cases of deafness in children of 5 to 10 years of age the diagnosis of juvenile otosclerosis was sometimes made with some confidence on the basis chiefly of a negative Rinne test. It seemed to him that had caloric and absolute bone conduction tests been done in Mr. Simson Hall's case a different view might have been taken of the diagnosis.

Section of Orthopædics

President—NORMAN CAPENER, F.R.C.S.

[*October* 4, 1949, *contd.*]

Bone Dystrophy of Unknown Ætiology (Presented for Diagnosis).—H. H. LANGSTON, F.R.C.S.

F. H., aged 48, was referred to the Orthopædic Out-patient Department on account of painful knees.

FIG. 1.—F. H.

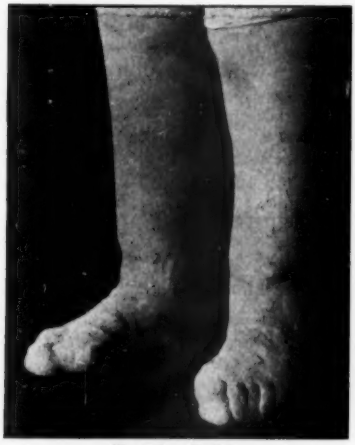

FIG. 2.—F. H.

FIG. 3.—D. S.

FIG. 4.—D. S.

FIGS. 1–4.—Show bone dystrophy of unknown ætiology in a brother and sister, illustrating marked clubbing of fingers, lower ends of tibiæ and toes.

On examination.—Healthy man with no evidence of cardiac or pulmonary abnormality. There was present marked bilateral enlargement of the lower ends of the radius and ulna, of the femora and of the tibiæ, with clubbing of the fingers and toes. Patient stated that the clubbing had been present for as long as he could remember, and was quite definitely present in adolescence.

X-rays show marked enlargement of the lower ends of the radii and ulnæ, femora and tibiæ. This enlargement appears to be due to long-standing periosteal new bone formation. On the surface of the bone around the enlarged ends are numerous small bony projections.

Pathological investigations.—Serum phosphate, inorganic 4·5 mg.%, serum calcium 9·9 mg.%, serum phosphatase—acid 0·6 K. and A. units, alkaline 4·8 K. and A. units.

W.R. negative. Complete and differential blood-count: No abnormality.

Family history.—Patient is one of eight brothers and three sisters. One sister (D. S.), aged 58, has a precisely similar bone dystrophy (*see* photographs and X-rays). All brothers and sisters have multiple cutaneous fibromata. The affected sister states that the condition in her case has also been present for as long as she can remember. Both patients have led healthy active lives and have suffered no inconvenience from the disability until the present time. Both are now beginning to develop symptoms from the onset of osteo-arthritis.

FIG. 14.—D. S.

FIGS. 9–14.—Long bones of F. H. and D. S., illustrating marked clubbing, particularly of the lower end of the radius and tibia with irregular periosteal new bone formation.

Sir Thomas Fairbank said he had seen this case and the man's sister some months ago with Mr. Langston and had since tried to find a comparable published case. A useful paper was one published by Uehlinger under the title Hyperostosis Generalisata mit Pachydermie (Idiopathische Familiäre Generalisata Osteophytose) in Virchow's *Archiv. Path. Anat. Physiol.*, 1941, **308**, 396. Though Uehlinger's case is not strictly comparable with the present case—the bones are coarsely striated in addition to the hyperostosis—he discusses a variety of published cases, a few of which are of interest. Mr. Langston's case was certainly not one of hypertrophic osteoarthropathy in his opinion.

NOTE.—On further research, the cases which seem to show the closest similarity to Mr. Langston's are a brother and sister reported by Mankowsky *et al.*, *Fortschr. Röntgenstr.*, 1934, **50**, 542.—H. A. T. F.

[*November* 1, 1949]

Leri's Disease (Melorheostosis).—G. P. ARDEN, F.R.C.S.

Female, aged 13 years.

Family history.—Nothing relevant. I saw this patient two years ago, on account of hallux rigidus of the left big toe. The X-ray photograph of the foot showed a streaky condensation of dense bone (Fig. 3). This was also found to involve the left tibia, the femur, and a small portion of the acetabulum (Figs. 1, 2A, 2B). On examination there was

FIG. 1.

FIG. 3.

FIG. 2A.

FIG. 2B.

FIG. 1.—Streaky condensation of dense bone running up neck of femur from the shaft, also involving upper margin of acetabulum. Some cortical thickening inner side of left femur just below lesser trochanter.

FIG. 2A.—Dense striæ of bone in upper tibia crossing epiphyseal line into external tibial condyle affecting upper fibular epiphysis, patella and femur. Several rounded areas of dense bone in both lateral tibial and femoral epiphyses.

FIG. 2B.—Streaky condensation in lower femur, patella and upper tibia.

FIG. 3.—Left foot showing streaky condensation of bone affecting tarsal bones and lower tibia.

limitation of movement, not only of the big toe-joint, but of the ankle, knee and left hip-joint and two inches shortening of the left leg. The patient had had no pain but only limitation of movement. This condition appears to begin in childhood and is more common in males than females, it usually affects one limb. One case has been described as Leri's disease and also osteopoikilosis. Another complication which is sometimes seen is sclerodermia of the skin, but there was no sign of that in this case. The condition tended to progress when followed up for some years. The treatment in this case had merely been to raise the left shoe by 2 inches and a Kellar's operation had been performed on the left big toe.

The President said that he found it difficult to accept this case as a straightforward one of melorheostosis. The intra-osseous condensations in the tibia suggested Albers-Schönberg's disease.

Osteopoikilosis Affecting Right Foot and Other Bones.—G. P. ARDEN, F.R.C.S.

This patient was referred to me by Mr. Lovelock-Jones as a case of osteopoikilosis.

Female, aged 36, first came to the out-patients' department with swelling of the right ankle of a few weeks' duration. The X-ray picture revealed osteopoikilosis (Figs. 4A and 4B). She had had no trouble previously and X-rays of her small daughter showed a normal condition. Further X-ray examination revealed generalized bony changes mainly affecting both feet, hands, hips and shoulders (Figs. 1, 2, 3). There was some œdema of the right ankle, otherwise the patient was quite fit.

This condition was first described in 1905, but much more fully in 1915 by Albers-Schönberg. This again was more common in males than females. There was some tendency for the spots to join up and form striæ. The condition may progress or remain stationary. The œdema of ankle in this case suggested an early sclerodermia, but I can find no reference to this complication in other cases.

FIG. 1.—Several areas of dense bone in neck of both femora tending to form striæ. Both ischii also affected.

FIG. 2.

FIG. 2.—Few scattered dense areas in head of humerus and acromium.

FIG. 3.—Scattered areas of dense bone mainly affecting the carpal bones. (Both hands affected.)

FIG. 3.

FIG. 4A.

FIG. 4B.

FIGS. 4A and 4B.—Multiple small rounded areas of condensation affecting tarsal and metatarsal bones.

Sacral Spina Bifida and Meningocele.—K. I. NISSEN, F.R.C.S.

A cobbler, aged 43. He had a sacral spina bifida and a large meningocele with complete urinary incontinence. There was severe bilateral talipes equino-varus, with chronic ulceration of the soles of both feet (Fig. 1). The ulcers on the left side commenced at 23 and on the right at 34; they caused recurrent but almost painless cellulitis of both feet. Apart from its bulk the meningocele itself gave little trouble, although pressure upon it caused headache. His rubber urinal was liable to spill and he also suffered from deafness.

FIG. 1.

FIG. 1.—Severe bilateral talipes equino-varus with chronic painless ulceration.

FIG. 2.—Showing meningocele and double below-knee amputation.

FIG. 2.

When first seen in January 1949 he was severely disabled on account of his grossly deformed and deeply ulcerated feet. After yet another flare of infection, the patient agreed to bilateral below-knee amputation. This was done in July and in August, and in September the patient was fitted with temporary Durestos pylons (Fig. 2). He walked well in a few days, possibly because he was used to partly insensitive limbs which afforded him little information. Standard below-knee limbs from Roehampton, and a hearing-aid for severe deafness, are both on order. In view of imperfect bowel control, transplantation of the ureters could not be entertained, but an improved (Donald Rose) urine-collecting apparatus has proved very satisfactory. This patient had become almost a social outcast, but the improvement in his general health and mental outlook is already remarkable.

The President said he was rather interested in Mr. Nissen's case of lumbar meningocele. He recalled that Sir Thomas Fairbanks told him on one occasion that he had long ceased to operate on spina bifida. Miss Forrester-Brown recently had demonstrated a cup-shaped device made of Perspex which she placed over such lesions in babies to give protection. The meningoceles had regressed, and even, in a certain number, had disappeared.

Spondylitis Ankylopoietica with Deformity of the Cervical Spine.—K. 1. NISSEN, F.R.C.S.

This man, a street-trader, aged 52, had used a motor-chair for many years, but found that his restricted range of vision made driving unsafe. Three plastic cervical collars had been made with a useful degree of correction of the cervical deformity and with loss of painful fatigue of the neck muscles (Fig. 1).

FIG. 1.—The deformed cervical spine supported by a polyethylene collar.

Dr. John Scales: Mr. Nissen's cases illustrate the use of two plastic materials—Durestos and polyethylene. The former material is used in aircraft construction and the latter for electrical insulation and plumbing.

Durestos arrives in fairly rigid sheets. When damped with water the material becomes very malleable and can be stretched to cover any shape. A positive plaster cast is needed for moulding the material, which cannot be applied directly to the patient. It is "cured" by heating in an oven at 70° C., after which there is no danger of contact dermatitis.

To make an above-knee pylon like the one exhibited to the Section, about four thicknesses are used, but over the ischial weight-bearing area, up to ten thicknesses; the bucket and peg down to the heel are made in one. The finished pylon, weighing only some two pounds, may need to be weighted for better control.

The other material, polyethylene, a polymer of ethylene, is a typical thermoplastic material. A flat sheet is taken and tailored roughly to shape. For a cervical collar the back and front parts are cut out and put on to an asbestos board. The material is heated up to 119° C. in a gas-oven; when it becomes clear, it is ready for moulding. Reinforcing strips of the same material can be put on if required and readily fuse at 119° C. Polyethylene is waxy in appearance and feel, and is resilient. It does not tear or break, having no internal stresses when moulded. Ventilation is obtained by drilling holes.

Osteomyelitis of the Acetabulum with Intra-pelvic Protrusion of the Head of the Femur.—K. I. NISSEN, F.R.C.S.

Woman, aged 50. She developed a staphylococcal infection of the inner wall of the acetabulum and of the hip-joint in East Africa. By the time of her arrival in England, the head of the femur had entered the pelvis (Fig. 1), an abscess in the groin had left a chronic sinus, the leg was grossly œdematous, and the blood picture showed a severe toxic anæmia. The anti-α-hæmolysin titre was 20 international units, a very high figure.

The head and neck of the femur were excised through an incision which allowed access both to the hip and to the head lying beneath the iliopsoas muscle. Post-operatively skeletal traction through a tibial pin was used, with care to avoid external rotation. By the fourteenth day the sinus had closed, the wound was healed, and the range of flexion was 100 degrees. As the capsule at operation had been half an inch thick, it was thought that fibrosis would give stability of the pseudarthrosis sufficient to avoid the use of a caliper.

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 1.—Showing the intrapelvic protrusion of the head of the femur through the softened inner wall of the acetabulum.

FIG. 2.—Four months after excision of the head and neck, the trochanters were raised and the pseudarthrosis was unstable.

FIG. 3.—Four months after a plate osteotomy and two months of weight-bearing the pseudarthrosis appears stable.

After three months of crutches and non-weight-bearing, however, the trochanter was riding high and the joint was obviously unstable (Fig. 2). The plated osteotomy described by Batchelor was therefore performed and, with tibial traction as before, bone union was sound at eight weeks. The range of passive flexion on return to East Africa was 110 degrees and the range of abduction and adduction was fully equal to that on the normal side (Fig. 3). Shortening was 1¼ inches, and the patient walked well with one stick and a raised heel. The physical treatment after each operation was simplified by using a method of skeletal traction which has been found to have a number of practical advantages (Fig. 4).

The apparatus is based upon the long U-loop used by Tulloch Brown of Glasgow, which is a four-foot length of aluminium bar, ⅛ inch by ¼ inch in cross section, bent into a U with an inside width of 4½ inches. The end of each side bar has several holes drilled in a zig-zag order over a length of some 3 inches. These holes allow the side-bars to be threaded over the ends of the Steinmann pin outside the fixed bushes of a Steinmann stirrup. The series of holes makes allowance for variation in the length of the lower leg, but, more important, permits the U-loop to be inclined to one or other side in order to give equal clearance at the malleoli. With the calf supported by slings, suspension is obtained from a cord attached to the stirrup and traction from a horizontal cord attached to the end of the U-loop.

The traction apparatus in use at Stanmore has the following modifications (Fig. 4):

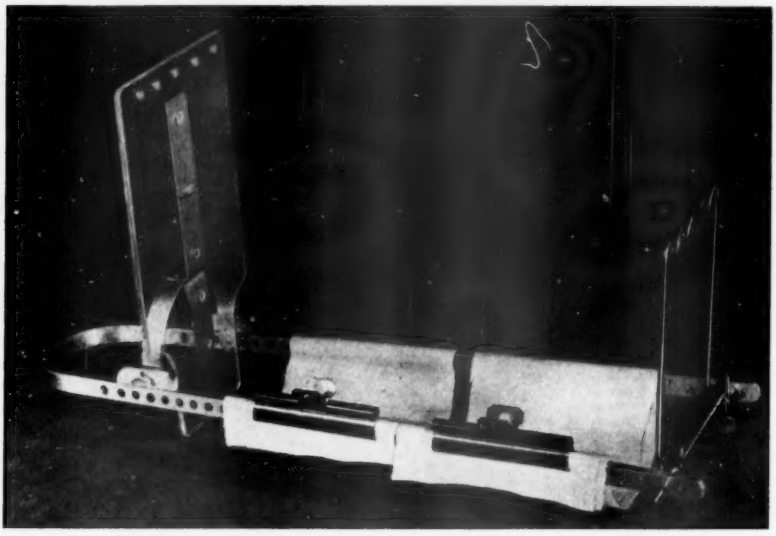

FIG. 4.—Tulloch Brown's U-loop with adjustable foot-piece and modified Steinmann stirrup.

(1) A detachable foot-piece has been designed which can be set in any pair of a number of opposing holes drilled $\frac{1}{2}$ inch apart. The foot-plate is of Perspex and measures 12 by 6 inches. It is attached to a semi-circle of spring steel which has at either end a stud to fit the holes and a horizontal lug fitting along the upper margin of the side-bar to restrain rocking. The foot-piece, which is mainly for use at night, gives flat support to the forefoot, and being springy, is excellent for resisted exercise of the calf muscles. A series of holes along the top of the foot-plate are for the attachment of cords or preferably of coiled springs for free swinging exercises.

(2) The standard Steinmann stirrup has been entirely re-designed. The bushes are much heavier and thumb-screws of stout gauge ensure efficient fixation. Each end of the stirrup wire is shaped like a crook so that it can be slipped on or off its bearing with a little pressure. Any rotation strain transmitted from the wire to the bushes and hence to the pin is negligible. The middle part of the stirrup, usually twisted into a circle, is now wavy, with a choice of five upward curves for suspension. The outer curves are particularly useful when external rotation of the limb has to be controlled. The whole stirrup can be taken apart into its three pieces or assembled again in a moment; this avoids all difficulty in threading a stirrup over the ends of a long pin.

The complete apparatus has been found of value in the treatment of various types of fractures of the femur, but especially for the first month after cup arthroplasty or Batchelor's pseudarthrosis operation, when both traction and free movements are required but external rotation must be avoided.

The President showed radiographs of a case of **Progressive Myositis Ossificans.**

Clinical Section

President—W. A. BOURNE, M.D.

Rheumatic Aortic Incompetence with Delayed Diastolic Murmurs on Auscultation

By AUBREY LEATHAM, M.R.C.P.
(*From the Cardiac Department of the London Hospital*)

AORTIC diastolic murmurs begin immediately after the second sound (Fig. 1). Wells, Rappaport and Sprague (1949) have shown that the crescendo of the murmur often occurs later on the phonocardiogram (Fig. 2). Recently we have seen two patients at the London Hospital in whom the aortic diastolic murmur seemed on auscultation to be separated from the second sound by a distinct gap; and caused difficulty in diagnosis. Phonocardiograms in each case show that diastolic vibrations begin at the second sound, but the main murmur comes later.

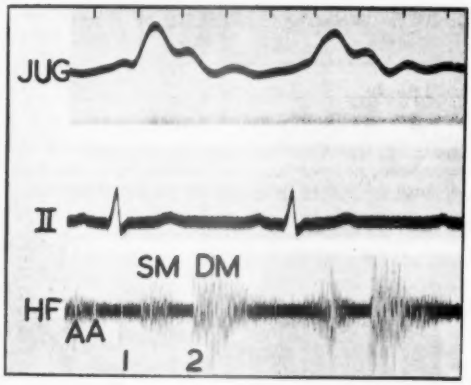

FIG. 1.—Aortic incompetence with typical diastolic murmur on auscultation. Synchronous jugular tracing, electrocardiogram lead II, and high frequency (HF) sound recording from the aortic area (AA). The aortic diastolic murmur begins immediately after the second sound.

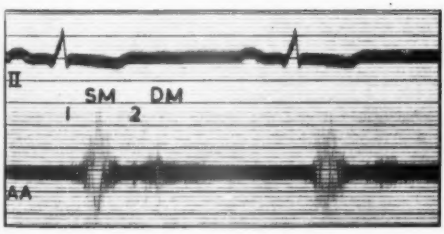

FIG. 2.—Aortic stenosis and incompetence with typical diastolic murmur on auscultation. On the phonocardiogram the diastolic murmur, though following the second sound, is maximal later.

Case I.—Mrs. F., aged 36, had chorea at the age of 7 and again at 9 years. The heart was first in question at the age of 16. Now she has slight palpitation but no other symptoms, not even breathlessness on exertion. The pulse is slightly collapsing in quality and the blood pressure is 140/60. External to the apex there are presystolic and mid-diastolic murmurs of mitral stenosis, but they are localized to a small area and only clearly heard after exertion. There is no systolic murmur. The outstanding physical sign is a loud diastolic murmur at the lower left sternal edge. The murmur is high pitched like any aortic diastolic murmur, but its remarkable feature is a gap between the second sound and the onset of this murmur; for this reason the patient was referred by Dr. William Evans for phonocardiography. A high-frequency (Leatham, 1949) sound recording from the lower left sternal edge (Fig. 3) confirms that the main aortic diastolic murmur is late and begins over 1/10 sec. after the second sound, but some vibrations, not enough to be audible, begin immediately after the second sound. That aortic valve disease is the main lesion is supported by finding left ventricular preponderance in the electrocardiogram and left ventricular enlargement on cardioscopy, with equivocal radiological evidence of mitral stenosis as the subsidiary lesion.

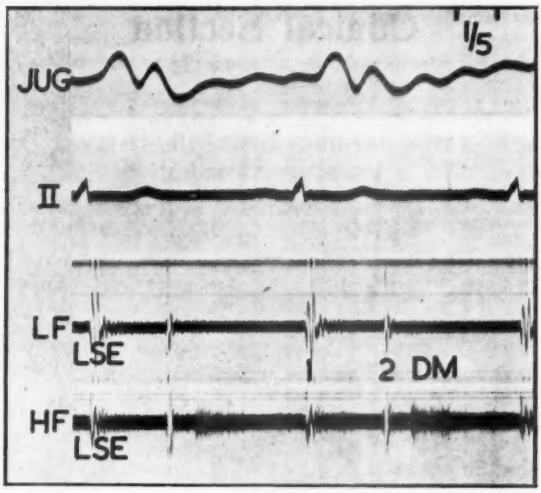

FIG. 3.

FIG. 3.—Aortic incompetence with delayed diastolic murmur on auscultation (Case I). A high frequency recording from the left sternal edge (LSE) shows that the main murmur begins over 1/10 sec. after the second sound, though some vibrations, not enough to be audible, begin immediately after the second sound. The murmur is too high pitched to be shown in the low frequency (LF) recording from the same area.

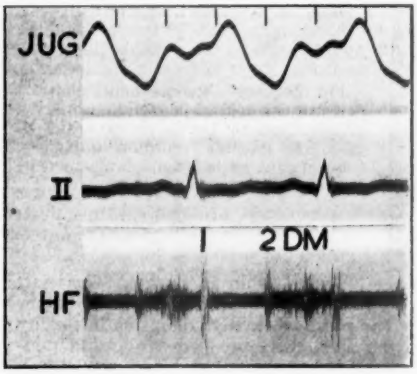

FIG. 4.

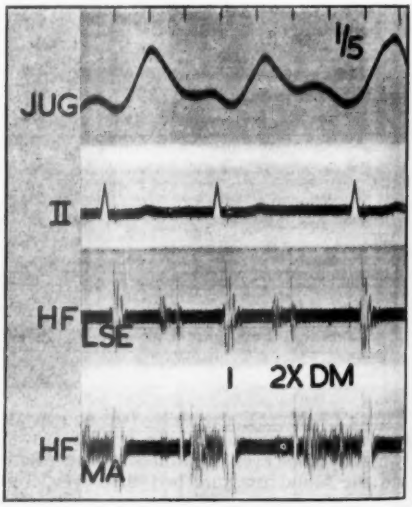

FIG. 5.

FIG. 4.—Aortic incompetence with delayed diastolic murmur on auscultation (Case II). A high-frequency recording from the left sternal edge shows that the main diastolic murmur is late though some vibrations begin immediately after the second sound.

FIG. 5.—The phonocardiogram of a patient with mitral stenosis for comparison with those of aortic incompetence. High-frequency recordings from the apex (MA) and synchronously from the left sternal edge (LSE) show the second sound, a gap, the opening snap (X) separated by a short interval from the mid-diastolic murmur of mitral stenosis. The vibrations immediately after the second sound are probably due to a slight degree of aortic incompetence.

Case II.—Miss C., aged 28, had rheumatic fever at the ages of 13, 18 and 20 years. Following the last attack she was told that her heart was affected. Now she has no symptoms. The pulse is moderately collapsing in quality and the blood pressure is 165/60. At the lower left sternal edge there is a loud high-pitched diastolic murmur separated from the second sound by a gap. The phonocardiogram (Fig. 4) confirms that the main diastolic murmur is late though some vibrations begin immediately after the second sound. The presence of aortic valve disease is supported by left ventricular preponderance in the electrocardiogram and slight left ventricular enlargement on cardioscopy. There is no clinical or radiological evidence of mitral valve disease.

The phonocardiogram (Fig. 5) of a man aged 43 with mitral stenosis is shown for comparison with the records of aortic incompetence and unusual diastolic murmurs. At the apex (MA) there is an obvious mid-diastolic murmur; here and at the lower left sternal edge (LSE) there is a loud sound (X) following the second sound, the so-called "opening snap" of the mitral valve. It precedes the mid-diastolic murmur by a short interval. Between the second sound and the "opening snap" are some vibrations which probably represent the early diastolic murmur of aortic incompetence which was just audible on auscultation.

In conclusion, it is well known that aortic diastolic murmurs begin immediately after the second sound but graphically this murmur may be shown to be maximal later. In rare cases the late crescendo may create the auscultatory impression that the murmur is separated from the second sound by a gap. This may cause difficulty in diagnosis though the murmur may be otherwise typical of aortic incompetence in its location and high pitch.

My thanks are due to Dr. William Evans for referring both cases to me.

Constrictive Pericarditis and Mitral Stenosis.—FREDERIC JACKSON, M.R.C.P.

The patient, a male aged 52, had rheumatic fever three times in childhood. He had no known contact with tuberculosis. All his life he had been a little short of breath on exertion but had worked as a farmer until the age of 47.

FIG. 1.

FIG. 2.

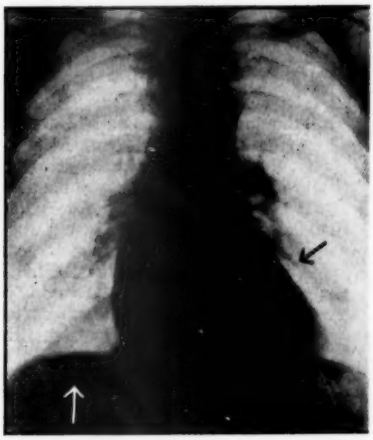

FIG. 3.

FIGS. 1 and 2.—Anterior and left oblique views. Slight enlargment of the heart. Calcium in the pericardium and in the dome of the right diaphragm.

FIG. 3.—Right oblique view. Left auricular impression on the barium-filled œsophagus.

In 1946 he was seen with symptoms of heart failure of two years' duration. His pulse (70–80 a minute) was irregular from auricular fibrillation; the venous pressure was raised (13 cm. of water); the liver was enlarged, but there was neither ascites nor œdema. A moderately loud systolic murmur was heard at the apex, but no diastolic murmur, and a third heart sound followed closely after the second sound.

On radiological examination the heart was slightly enlarged, calcium was seen in the pericardium (Figs. 1 and 2), and the left auricular impression on the barium-filled œsophagus was a little prominent (Fig. 3). In addition there was a plaque of calcium in the pleura over the right diaphragm (Figs. 1 and 2).

A diagnosis of mitral stenosis was considered but could not be proved. The venous distension and liver enlargement without other signs of failure in a man with moderately slow auricular fibrillation and clear triple rhythm suggested pericardial constriction. Calcium in the pericardium with minimal enlargement of the heart supported this view, and a diagnosis was made of constrictive pericarditis with probable rheumatic heart disease.

Pericardiectomy was performed by the late Mr. Tudor Edwards. The pericardium was thickened, densely fibrous and contained plaques of calcium; it was closely adherent to the heart, and it was stripped from both ventricles and the apex.

Since the operation the venous pressure has remained normal and the liver edge has receded, but symptomatic improvement has not been as favourable as expected. This may be due to additional mitral stenosis which can now be recognized by hearing a mid-diastolic murmur. The disappointing clinical improvement leads one to question the advisability of the operation in this case, despite the relief of the constriction and the lowering of the venous pressure.

Constrictive pericarditis is believed by many to be tuberculous in origin though evidence of the infection is frequently lacking. This case is likely to be an association of the effects of tuberculosis and rheumatic fever, two common diseases, existing together in the same patient. The difficulty remains, however, as to how far the symptoms must be ascribed to each.

Dr. A. Elkeles: Dr. Jackson's case is of special interest, since it shows that rheumatic fever can be an ætiological factor in the production of chronic adherent calcified pericarditis. I had the opportunity of investigating radiologically two cases of mitral stenosis with auricular fibrillation and signs of constrictive pericarditis. Oblique and lateral X-rays of the heart showed diffuse calcification of the pericardium. There was no evidence of tuberculosis. Mitral stenosis and tuberculosis exclude each other to some extent. In the past calcified opacities in the lungs sometimes met with in cases of mitral stenosis have been interpreted, probably wrongly, as evidence of pulmonary tuberculosis. In recent investigations Elkeles and Glynn (1946) have proved that some lesions can be due to intra-alveolar bone formations with no evidence of tuberculosis. Harkavy (1941) drew attention to the occurrence of constrictive pericarditis and even polyserositis in cases of severe vascular allergy with eosinophilia, in which the chief precipitating factor was bacterial allergy, resulting from chronic infection of the paranasal sinuses. In my opinion, the widely held view that tuberculosis is the most common ætiological factor in chronic adherent pericarditis has to be revised.

Xanthomatosis Peritonei. ? Carcinoma of the Bronchus.—J. S. STAFFURTH, M.D., M.R.C.P. (for REGINALD HILTON, M.D.).

G. P., a retired police sergeant, aged 64.

1942: Skin lesions first noticed. W.R. ++.

1947: At an operation for right inguinal hernia free fluid was found in the peritoneal cavity. The peritoneum itself was thickened and white, and on section showed chronic inflammatory change with a large number of foam cells. Blood cholesterol 97 mg.%.

April 1949: A hard irreducible lump appeared at the site of the previous hernia. At operation this was found to be a yellow tumour at the apex of a hernial sac. Free fluid was present in the peritoneal cavity.

Since then he has lost weight, the ascites has become more troublesome and for three months he has complained of hoarseness of voice. There is only slight cough.

. Family history is not relevant.

On examination.—The patient is thin. Xanthomatous deposits are present in both axillæ, elbows and in the inguinal folds; also along the margins of the eyelids and in the inner canthus of both eyes. There is diminished air entry of the left side of the chest with impaired percussion at the left base; considerable ascites; palpable liver; large spleen.

Investigations.—X-ray of chest shows a mass at the left hilum. Screening shows a paralysed left diaphragm. Blood cholesterol 70 mg.%. W.R. negative. Plasma proteins 4·4 grammes% (albumin 2·5, globulin 1·9 grammes%). Bronchoscopy: Immobile left cord; bronchial tree normal.

He has just completed a course of radiotherapy to the left hilar region, but as yet there is no improvement in symptoms and only slight change in the radiological appearance.

POSTSCRIPT (14.12.49).—Dr. G. B. Dowling's report reads: "There are large patches of superficial xanthomatosis in the axillæ, in the elbows, on the upper eyelids, in the post-auricular folds and in the inguino-crural areas." He stated that he had not seen lesions like this in xanthomatosis before.

Biopsy report (Dr. J. Bamforth): "Small clumps of foam cells chiefly associated with blood vessels are present in the lower part of the dermis and in the subcutaneous tissue." Dr. Dowling has seen this section and he has no doubt that the lesions are due to xanthomatosis.—J. S. S.

Dr. F. Parkes Weber said that foam cells might abound in some chronic inflammatory conditions (for instance, xanthomatous salpingitis) as well as in certain neoplastic conditions, including so-called xanthosarcoma and osteoclastoma. (Compare F. P. Weber on "Xanthomatous formations in inflammatory tissue and true tumours" in *Modern Trends in Dermatology*, London, 1948, p. 311.) The present case showed a chronic thickening of the peritoneum containing foam-cells, which perhaps might be termed "xanthomatosis peritonei", but the condition in the thorax was more likely to be a malignant neoplasm of quite different nature. He (F. P. Weber) could find no evidence of any cutaneous xanthomatosis as far as his single inspection and the illumination permitted.

POSTSCRIPT (16.11.49).—In some respects the peritoneal condition should be compared with that in the case termed "intestinal lipodystrophy" by C. H. Whipple, 1907, *Johns Hopk. Hosp. Bull.*, **18**, 382.—F. P. W.

Dr. G. E. Vilvandré: I have no doubt that the chest condition is malignant. The paralysed left dome of the diaphragm and a paralysed left vocal cord support this diagnosis, and in my opinion the lateral view is in favour of a bronchial neoplasm.

Irradiation and Diathermy Necrosis Right Breast with Intractable Pain. Treated by Excision of Ulcer and Transference of Left Breast with Dermatome Graft to Secondary Defect.—PATRICK CLARKSON, M.B., B.S., F.R.C.S.

E. M. T., female, aged 68.

May 1945: Pain in left breast for past three months. B.P. 260/120. Coronary thrombosis 1943.

1945: Radium implant for carcinoma of breast.

1947: Irradiation. This was followed by intractable pain and necrosis over the site of the right breast. Alcohol injection in 1947. No relief.

20.7.48: Excision of neoplastic ulcer; Mr. Anthony Green and Mr. F. D. Saner using diathermy. Partial cover by free graft later (P. C.).

In view of the dense fibrosis of the whole of the chest wall surrounding the ulcer and the extensive necrosis of ribs and cartilage, it was felt that a free graft would not provide a stable cover. Equally, a posterolateral flap from the same side was considered uncertain as all this tissue had been extensively irradiated. A flap therefore had to come from the opposite side. The most adjacent tissue was the opposite breast. It was considered safer to do this breast transference in two stages.

30.12.48: Local excision of sloughs and superficial necrotic cartilage and bone. Delay of left breast flap (*see* Fig. 1).

FIG. 1.—Left breast "delayed". At same operation sequestrectomy and removal of sloughs from surface of radiation ulcer.

FIG. 2.—Post-operative result. Ulcer plus an area 6 in. across of scar tissue has been excised and the left breast swung over the defect with a dermatome graft to the secondary defect on the left.

15.1.49: Radical excision of scarred area including "clean ulcer" and 6 in. of fifth and sixth chondro-costal junctions. Defect of 6 in. diameter established. Transference of left breast over this raw area on right. Dermatome graft to secondary defect on left.

Healing complete three to four weeks later (Fig. 2). Complete relief of pain with increase in weight and appetite, and relief of insomnia.

Rheumatoid Arthritis Following Thyrotoxicosis.—FRANCIS BACH, D.M.

F. T. B., male, aged 30.

Previous history.—Whilst in the R.A.M.C. at the age of 20, he first noticed loss of weight, increased sweating and fatigue. Some protuberance of his eyes was then present. One year later he received a course of deep X-ray therapy at Leeds Infirmary for thyrotoxicosis. He was discharged from the Army in June 1942 and remained well until July 1943, when his symptoms returned, with frequent attacks of palpitation, and he was admitted to St. Bartholomew's Hospital. His basal metabolic rate was within normal limits but, in view of his symptoms, a partial thyroidectomy was carried out in October 1943. His general health improved and sweating diminished.

Within one month of his discharge from hospital, he developed an acute polyarthritis of the rheumatoid type, with a rapid onset of contractures and deformity and, within a year, he was completely crippled. He was transferred to Bath and treated with gold; his general weakness precluded hydrotherapy.

On admission to St. Stephen's Hospital, 1944, he was completely crippled, with advanced rheumatoid arthritis. There was marked flexion deformity with spasm of the muscles of the hip, knee and shoulder joints.

Blood count.—R.B.C. 4,190,000; Hb 71%; C.I. 0·8; W.B.C. 7,900 per c.mm. E.S.R. 80 mm. in 1 hr. (Westergren). Blood cholesterol and serum proteins normal.

There was no response to general medical treatment and, in December 1944, it was decided to perform a splenectomy. This was followed by marked improvement in his general health, relief of muscle spasm and the return of his sedimentation rate to the upper limits of the normal by April 1945.

During the next few years, a series of manipulations and reconstructive operations were carried out with the aim of making him fit to return to a sedentary occupation. In April 1949 he was transferred to Queen Mary's Hospital, Roehampton, to await the provision of a motor chair in order that he might return to his clerical employment.

This patient is shown to stimulate discussion on the relationship of the spleen, thyroid and adrenal cortex to rheumatoid arthritis, and to ask advice on: (*a*) the relationship of the thyroid and adrenal glands to rheumatoid arthritis, and (*b*) the role of the spleen in this disorder.

Comment.—In 1940 with Oswald Savage, I reported 3 patients under my care in whom splenectomy had been performed, and reviewed the literature on the subject (*Ann. rheum. Dis.*, 1940, **2**, 47).

In 1946, I presented at this Section a young woman in whom a rheumatoid type of arthritis had been quiescent following splenectomy (*Proc. R. Soc. Med.*, 1946, **39**, 306). I then suggested that rheumatoid arthritis was a psychosomatic syndrome in which metabolic and psychological factors appeared to play a more important role than did focal infection, and pointed out that in starvation, pregnancy and jaundice there is often a dramatic diminution in the severity of the symptoms but improvement was, unfortunately, only of short duration. I suggested that, in these conditions as well as that following splenectomy for acholuric jaundice there is a retention of cholesterol in the blood, and that cholesterol has been claimed as the mother substance of hormones, vitamins and carcinogenous substances. From the oxidation of certain side-chains of the cholesterol formula are derived: (*a*) the nucleus of bile salts, (*b*) testosterone, (*c*) steroids of the adrenal cortex, (*d*) stilbœstrol, all substances which are used by clinicians in the treatment of rheumatoid arthritis.

Last year Compound E, now known as Cortisone, and A.C.T.H. (adrenocorticotrophic hormone) attracted much attention following the magnificent work of Kendall and Hench of the Mayo Clinic and Thorn of Boston.

This year, at the Mayo Clinic, I was privileged to see the dramatic clinical response to injections of Compound E in rheumatoid arthritis. This demonstrated the "clinical reversibility" of this "potentially reversible disease" (Hench). Unfortunately, the clinical response occurs only if massive doses (much above physiological levels) are given (100 mg. daily parenterally).

Cortisone is not and, in my opinion, will not be the *treatment* for rheumatoid arthritis. It is someone else in the endocrine orchestra who is the villain. The fault may lie in a man's philosophy of life, his psychological reactions, his hypothalamus, pituitary, adrenals or in his spleen. A psychological approach by a general physician plays an important role in prevention and early treatment. Surgical intervention must necessarily be a crude method of treatment.

The recent papers of Professor Means and others (*Lancet*, 1949 (ii), 543) have pointed out the close association of the thyrotrophic and the adrenotrophic hormones. In thyrotoxicosis, the secretion of both is increased, in myxœdema diminished.

In this patient, thyroidectomy was followed immediately by an acute rheumatoid arthritis. Was this due to a sudden cutting down of the adrenocortical hormone, thus producing

the clinical picture of rheumatoid arthritis? Was this "potentially reversible disease" reversed by removal of the patient's spleen?

Mr. T. Levitt stressed that although rheumatoid arthritis did not accompany thyrotoxicosis frequently, patients with joint pains had shown some improvement after thyroidectomy. The case, however, presented important features showing that the exophthalmos was of a type which one would classify as "malignant", that is, it would not improve after thyroidectomy.

At the Thyroid Clinic, New End Hospital, cases of prominent eyeballs were classified as follows: (1) *Pseudo-exophthalmos*, which was essentially a condition of lid-lag and would usually be cured by thyroidectomy;

(2) *True exophthalmos*, consisting of two types: (*a*) The *benign* group. Here the protruding eyeballs were neither tense nor tender and could be pushed back into the orbit quite easily. This condition was due to an excess of retro-orbital fat. It had been cured successfully by an intra-orbital operation, originated and practised by Mr. J. E. Piercy, in which this excess of indurated fat was excised. (*b*) The "*malignant*" group presented tense, tender and protuberant eyeballs simulating an elastic ball which could not be pushed back into the orbit. There was no excess of indurated fat. An operation of the Naffziger type was required where part of the bony confines of the orbit was removed.

Intraspinal Neurofibroma and ? Neurofibroma of Neck.—J. F. BUCHAN, M.B., M.R.C.P. (for ERNEST FLETCHER, M.D.).

M. M., male, aged 43. A dyer and cleaner.

Admitted 27.6.49 to Royal Free Hospital, Unit of Rheumatology, complaining of pain in the right hip and down the outer side of the right thigh and in the right knee.

The pain originally came on suddenly in 1937, after defæcation. Treated with various mixtures and physiotherapy without relief. Eighteen months ago pain became much worse and the patient lost weight (9·6 kilos) and much sleep. Treated with intramuscular injections of benzyl salicylate and later by the application of a plaster jacket, in each case without relief of pain.

There was nothing relevant in the past or family history.

On admission.—General condition good. Hard lump deep to L. sternocleidomastoid muscle. Limitation of all movements in the dorsal and lumbar spine and a gradual kyphoscoliosis. Spasm of erectores spinæ. Weakness of flexors of R. hip. Wasting of R. thigh. R. knee-jerk absent, left very sluggish. Both ankle-jerks present and equal. Plantar responses flexor. Diminution in sensation in the distribution of L.3. Lumbar puncture: Froin's syndrome; initial pressure 195 mm. H_2O, with complete spinal block.

FIG. 1.—X-ray of lumbar spine showing changes in the twelfth thoracic and first lumbar vertebræ brought about by an intraspinal neurofibroma.

M. M. was transferred to the Atkinson Morley Hospital on 25.7.49. X-rays of the lumbar spine, A-P views, showed that the peduncles of the twelfth thoracic and of the first lumbar vertebræ were abnormally widely separated. Lateral views (Fig. 1) showed erosions of the pedicles of the same vertebræ, on the left side, and also of the posterior aspects of the bodies. The left D.12–L.1 vertebral foramen was much enlarged.

Mr. Valentine Logue found a very large neurofibroma arising probably from the first and second right lumbar nerves and extending out through the intervertebral foramen. Owing to its large size the intraspinal part of the tumour was removed piecemeal. The nerve roots of the cauda equina had been pushed over to the left and were much flattened, as was the conus medullaris, by the tumour.

Pain disappeared post-operatively but the weakness of the right quadriceps has not improved much.

This is the second case seen during the last two and a half years at the Royal Free Hospital, Unit of Rheumatology. During this time 596 cases have been admitted.

Camp and Adson (1931) and Brailsford (1948) clearly describe the radiological changes found in a case of this kind.

Mediastinal Abscess Following Removal of Foreign Body from Œsophagus with Subsequent Pharyngo-œsophageal Diverticulum.—H. WOLFSOHN, M.D., M.R.C.P.

Mrs. L. W., aged 37.

Ingestion of foreign body.—Admitted to St. Mary Abbots Hospital on 11.2.49 with severe discomfort after a fish meal the previous evening. Radiography revealed a metal wire at the upper end of the œsophagus which was removed by œsophagoscopy (Mr. S. Beards). After this she had four attacks of fever at home which subsided in 3 to 7 days.

Mediastinitis and abscess formation.—On 4.5.49 she was readmitted in a very ill condition complaining of a dry irritating cough, breathlessness, substernal pain and hoarseness of voice. Temperature 104·4°. X-ray (Fig. 1) showed a rounded opacity in the right lower

FIG. 1.—Central rounded opacity in the right upper chest. Mediastinal abscess.

FIG. 2.—Pharyngo-œsophageal diverticulum. The mediastinal abscess is no longer seen.

paratracheal zone. This soon spread into the right upper lung fields, then diminished in size and had practically disappeared six weeks later. Non-hæmolytic streptococci, micrococci, pneumococci, *Staph. albus* and diphtheroids were grown from the sputum but no tubercle bacilli. A barium swallow on 20.5.49 demonstrated slight cardiospasm and doubtful irregular indentation along the posterior pharyngeal wall opposite D3 to D5.

Treatment.—Procaine penicillin in oil 300,000 units daily with penicillin inhalations from 4.5.49 to 5.6.49. She was then symptomatically improved although still pyrexial (98°–100° F.). Streptomycin (0·5 gramme eight-hourly) was given from 5.6.49 until 13.6.49, after which her temperature was normal with an occasional rise to 98·6° F.

7.7.49: Discharged to a convalescent home. E.S.R. was still 24 mm./hour, but she was feeling well and gaining weight.

Œsophageal diverticulum.—After returning from the convalescent home on 28.7.49 she complained of an odd clicking sound when swallowing certain solids. There was a tendency to regurgitation of undigested food shortly after swallowing.

Barium swallow examinations (15.9.49 and 25.10.49) revealed a pouch (Fig. 2) arising from the posterior wall of the hypopharynx at the level of C6 extending to D1.

Comment.—The diverticulum arises in the classical position in the hypopharynx. It is of very recent onset as (*a*) symptoms of dysphagia, regurgitation of food and the clicking sound only occurred in July, (*b*) a barium swallow in May had failed to show the presence of a pouch, and (*c*) on œsophagoscopy in February no such pouch was seen. The trauma produced by the foreign body and the subsequent local inflammation which also led to mediastinitis are considered to have further damaged the potentially weak "pharyngeal dimple" between the oblique and cricopharyngeal fibres of the inferior constrictor muscle. This produced herniation of the mucosa and submucosa and, in consequence, a typical pulsion diverticulum.

POSTSCRIPT.—Treatment by surgical removal has been successful. H. W.

Section of Laryngology

President—R. D. Owen, B.Sc., F.R.C.S.

DISCUSSION ON THE TONSIL AND ADENOID PROBLEM

R. S. Illingworth (Professor of Child Health, The University of Sheffield): The remarkable antipathy possessed by many for the tonsil is exemplified by the work of Denzer and Felshin (1943). They examined 1,000 11-year-old New York school children and found that 610 had had their tonsils removed. The remaining 390 were referred to 20 school medical officers, and all but 65 were advised to have the tonsils taken out. Glover (1938, 1944, 1948) has drawn attention to the great frequency of the operation in this country and to the remarkable variation in its incidence from town to town. Glover (1948), Colins and Sydenstricker (1927), Kaiser (1930), Paton (1928, 1943), pointed out that the operation is performed much more frequently in the rich than in the poor. Whereas in elementary schools in this country about 20% of children have had the operation before the age of 14, 83% of new entrants to Eton in 1938 had had the tonsils out.

Difficulties in the Interpretation of Published Work

(1) *Failure to correlate bacteriological study of the tonsils with the disease for which they are removed.*—It would seem logical that if tonsils are to be removed as part of the treatment of acute nephritis, rheumatic fever, or other condition related to the hæmolytic streptococcus, only those tonsils should be removed in which there is evidence of that infection. Almost all papers fail to give such information, the writer's included (Illingworth, 1939*b*). Admittedly, the presence of hæmolytic streptococci in a throat swab does not prove that those organisms are the cause of the disease or represent anything more than the carrier state, but their presence would at least be a guide to rational treatment. It is possible, but unproved, that the removal of tonsils, in which there is a persistent hæmolytic streptococcal infection, might benefit the course of nephritis or rheumatic fever. Inclusion in statistical studies of the effect of operation in children with no such infection is very likely to obscure good results, if any, from an operation done for proper indications.

It is a well-recognized fact that a considerable proportion of cases of acute tonsillitis are due neither to the hæmolytic streptococcus nor to other known organisms, and are probably virus in origin. The commission on Acute Respiratory Disease (1946) in a three-year study of exudative tonsillitis and pharyngitis at Fort Bragg, found that only 25% showed satisfactory bacteriological evidence of streptococcal infection. In children suffering from recurrent tonsillitis the effect of the removal of those tonsils which were infected with the hæmolytic streptococcus might well be very different from that of removing tonsils in which there is no such infection. We have no information on that point.

There have been a few bacteriological studies of tonsils removed at operation, but little correlation between these findings and the symptoms of the patient. Caylor and Dick (1922) attempted to correlate a quantitative bacterial count in the tonsils removed at operation and the incidence of rheumatic fever. They found that clinical improvement occurred when heavily infected remnants were removed.

(2) *Unsatisfactory evidence of completeness of the operation.*—Very few papers on tonsillectomy give satisfactory evidence that the operation has been complete. Opinions as to the frequency of remnants differ considerably. Paton (1943) put the figure at "well over a third".

Gordon (1947) found remnants in 42·4% of 1,000 children who had had the operation. McLaggan (1930) found remnants in 49%, Clark (1913) in 42%, Rhoads and Dick (1928) in 73%, Campbell (1939) in 77·3%, Meyer (1946) said "I believe that complete tonsillectomies are performed rarely". It is possible that some of these so-called remnants represent merely compensatory hypertrophy of remaining lymphoid tissue. It is certainly unreasonable, in a condition such as nephritis or rheumatic fever, to compare the effect of tonsillectomy, when a remnant is left which may grow as large as the original tonsils with the effect of leaving the tonsils intact. The possible good results of the operation are obscured by poor results arising from poor operative technique. Rhoads and Dick (1928), Campbell and Warner (1930), and Meyer (1946) have all discussed the good results achieved by removing infected tonsil remnants. Caylor and Dick (1922) found that one tonsillar remnant examined by them contained more organisms than all other tonsils investigated. Campbell (1939) considered that such remnants are often a greater menace to a patient, both locally and generally, than the original tonsils.

The compensatory hypertrophy of remaining lymphoid tissue after the operation for tonsils and adenoids has often been discussed (e.g. Bordley, 1947; Crowe, 1944). Crowe stated that adenoids recur in 75% of children in whom the operation is done before puberty. It is uncertain whether this compensatory hypertrophy of lymphoid tissue is of value to the patient for the development of immunity, or of disadvantage to the patient as a nidus of infection. The literature does not compare the effect of medical treatment, in such conditions as rheumatic fever, with a really complete operation.

(3) *Persistence of infection.*—With very few exceptions the literature does not tell us whether the infection for which the operation has been performed has been removed or not. It is well known that a streptococcal infection commonly persists after the operation. If it does persist one can hardly expect the operation to prove an effective therapeutic measure. Longcope and co-workers (1935) stressed the importance of this persistence of infection after operation for nephritis. Allen and Baylor (1938) found that exacerbations of rheumatic fever were much more frequent in those children in whom infection persisted after tonsillectomy than in those in whom the infection was cured by operation.

(4) *Inadequacy of treatment.*—Bound up with the topics discussed above is the fact that in any clinical study, in which comparison is made between two lines of treatment, it is essential that in each case the treatment should be really adequate and thorough. Most of the literature on tonsillectomy merely compares the effect of the removal of the tonsils with that of leaving them intact. It does not compare the effect of proper medical treatment, including chemotherapy, with the effect of *complete* removal of tonsils and adenoids, in which there are no remnants, and in which any residual infection is properly treated by chemotherapy and other methods. Too often the throat is forgotten when once the tonsils have been removed. Once more, the good results of the operation, when properly performed for adequate reasons, and with proper after-care, are obscured by the bad results of inefficient techniques and inadequate post-operative treatment.

The writer is unaware of any study which compares the effect of tonsillectomy, for such conditions as recurrent tonsillitis, nephritis or rheumatic fever, with prophylactic chemotherapy designed to prevent streptococcal infection.

(5) *The combined or single operation.*—The literature leaves us very much in the dark as to whether the tonsils and adenoids should be removed in various conditions, or whether it is sufficient for only one or the other to be removed. Most of the literature concerns the combined operation.

(6) *The timing of the operation.*—This may be of importance in such diseases as nephritis, but it is hardly mentioned in the papers on the subject. It is possible that the operation would prove valuable if done early—but there is no evidence to that effect. Rudebeck (1946) found that the operation was of no value in nephritis, however early it was performed. There is a natural tendency to perform the operation when the disease has failed to respond to all other measures, or is already hopeless. There is evidence that the operation fails in those circumstances, but for reasons stated the investigations have been inadequate and do not prove that operation is never of value in the condition.

(7) *Methods of controlling.*—The method of controlling used in many papers has been unsatisfactory. Many papers fail to take the factor of age into account. A child is older after the operation than before it and the fact that he improves after the operation is no proof that the improvement is due to the operation. Most children develop a natural immunity to upper respiratory tract infections at the age of 6 or 7—the very age at which the peak incidence of tonsillectomy is reached. All comparisons of morbidity rates must be made in children of the same age group. Social factors, racial and geographical factors have to be taken into account. There is a higher incidence of streptococcal infections in some places than in others. Too often those factors are ignored in papers on tonsillectomy.

Many papers compare the health of those who have had the tonsils removed with that of children with intact tonsils. Many of these studies depend entirely on the history given by the mother. This is very apt to be fallacious. A mother who was anxious to have the operation performed is very likely to express satisfaction at the results of the operation and say that the child is better. Studies based on doctors' reports sent to school to explain a child's absence are somewhat more reliable. This sort of study helps little, however, for it is clear that those who have had the operation are likely to have had it for some reason, however bad that reason, and that there will be a higher incidence of colds, otitis and other infections in those submitted to operation than in controls. It is possible that those submitted to operation might have been worse if not operated on. Kaiser's investigation (1930), though one of the most careful, is not entirely satisfactory. He conducted a ten-year follow-up of 4,400 children who had been advised to have the operation. Half those children submitted to the operation, while the other half for various reasons were not operated upon. Subtle differences in the two groups reduce the value of the investigation. In the group of children who did not have the operation the parents may have been less co-operative and less intelligent, and so given a less accurate follow-up history of infections. There are many other difficulties in published work which make the interpretation of the results particularly difficult.

(8) *The duration of the follow-up.*—This has been inadequate in most papers. Kaiser showed how the incidence of colds and otitis media was less in the operated group for the first three years after the operation, but became greater thereafter than in the control group. It is possible that the operation caused a postponement of the age at which immunity to upper respiratory tract infections is normally developed.

(9) *Errors in diagnosis.*—Inaccuracy of diagnosis has led to many unnecessary operations. Once more the poor results of the operation done for improper indications obscure the good results of the operation done for proper reasons.

(*a*) *Sinus infections*: It seems certain that many of the symptoms for which tonsils and adenoids are removed are, in reality, due to infection of the nasal sinuses. Most papers make no mention of this. Crooks and Signy (1936) found infected sinuses in 24 out of 100 children at the time of tonsillectomy. 15 of the 100 children investigated had a chronic sinus infection. Griffiths (1937), Dean (1934), Selkirk and Mitchell (1931), Walker (1947), and others all emphasized the frequency of sinus infections in children sent up for tonsillectomy. Crooks (1938) found that only 9 out of 24 children with sinus infections were improved by tonsillectomy.

(*b*) *Adenoid facies*: This may be due to any nasal obstruction, and is not due merely to adenoids.

(*c*) *Mouth-breathing*: This may be due to several causes other than adenoids. It may be due to a habit, nasal obstruction, malocclusion or mental defect. Crooks (1938) said that there was mouth-breathing in 62% of his cases of chronic sinus infection. Epstein (1937) emphasized the frequent failure of adenoidectomy for the relief of mouth-breathing in children under the age of 6 years.

(*d*) *Colds*: So-called colds are often an allergic rhinitis or sinus infection.

(*e*) *Postnasal discharge*: This is often due to a sinus infection.

(*f*) *Growing pains*: Pains in the thighs rather than joints, are often wrongly called rheumatic fever. They do not respond to tonsillectomy, and, as far as is known, bear no relationship to the hæmolytic streptococcus.

(*g*) *Cervical adenitis.*—This is often due to dental caries, septic places on the face and scalp, and pediculosis capitis.

Other Difficulties Regarding Indications for Operation

(1) *Doubt about the function of the tonsil.*—It is generally thought that the function of the tonsil is that of immunity production. Most children acquire relative immunity to upper respiratory tract infections at the age of 6 or 7, and thereafter the tonsil decreases in size. It is possible that the regeneration of lymphoid tissue which follows the removal of tonsils and adenoids is designed by nature to help to produce that immunity. For this reason the complete destruction of lymphoid tissue by irradiation may or may not be altogether advisable.

Unfortunately we do not know at what stage the tonsil becomes more of danger than of value to its owner: there is no laboratory test which helps us to decide the question.

(2) *Focal sepsis.*—The problem has been adequately discussed by Reimann and Havens (1940) and others. We can certainly say that the theory of focal sepsis has largely fallen into disrepute, possibly for the same reason as the operation for the removal of tonsils—the great dilution of good results of treatment for proper indications with the bad results of random and unnecessary treatment.

(3) *Cervical adenitis.*—Many papers deal with the incidence of cervical adenitis before and after operation on the tonsils, and compare the incidence in children who have intact tonsils with that of children who have had them out. Most of these papers ignore the other common causes of cervical adenitis, mentioned above, and most make no attempt to define what is meant by cervical adenitis. What many would think normal others would think abnormal. Some define it as an adenitis which is visible. Few distinguish the non-suppurative from the suppurative form. Few papers, in fact, give us much help in assessing the value of the operation for the condition.

There seems little doubt that the fear of cervical adenitis is an exaggerated one. At one time it was thought that infected tonsils were the portal of entry for the tubercle bacillus. There is no evidence to this effect. It seems likely that many examples of tuberculosis of cervical lymph nodes, in adults at least, are due to infection via the blood stream, or infected sputum. Newhart and co-workers (1934) found that the tonsils of 48 out of 100 adults with pulmonary tuberculosis contained tuberculous foci, and Schlittler (1938) thought that most cases of tuberculosis of the tonsils in adults were due to infection from the lungs. The literature was reviewed by Rather (1943). We know that the tubercle bacillus can be recovered from the stomach washings in the great majority of children with primary lung tuberculosis, the organism having reached the stomach after being swallowed. We do not know how many cases of tuberculous cervical adenitis in children are of bovine and how many of human origin: but it is certainly advisable to take an X-ray of chest in all cases of tuberculous adenitis in children and to type tubercle bacilli which are recovered from glands which have broken down. It would not seem reasonable to perform a tonsillectomy for tuberculosis of the tonsils of human and therefore secondary origin.

In non-tuberculous cervical adenitis, as long as suppuration does not occur, there is no need to fear that the adenitis will harm the child. Enlarged nodes of this nature worry the mother, but not the child. Selkirk and Mitchell (1931) in their careful investigation found no evidence that the incidence of suppurative cervical adenitis is in any way reduced by the operation.

The extremely low incidence of cervical adenitis in the Basque school children who came to this country as refugees was noted by Ellis and Russell (1937): less than 2% of these children had had the tonsils removed.

(4) *Sore throat and tonsillitis.*—Some of the difficulties in the evaluation of published work on the subject have already been mentioned. Most papers ignore the difference between a sore throat at the commencement of a cold and a true tonsillitis. Most papers necessarily rely completely on the mother's history as to the frequency of tonsillitis. This history is notoriously inaccurate. The mother and father often disagree as to how often a child has tonsillitis. The finding of a follicular tonsillitis of which the parents are quite unaware and of which the child has not complained is commonplace. On the other hand a child may complain of a sore throat when inspection reveals nothing abnormal. Most papers on the effect of tonsillectomy on recurrent tonsillitis do not take these difficulties into account. It need hardly be added that true tonsillitis certainly should be rarer after the operation than before, just as appendicitis should be rarer after appendicectomy.

Another difficulty is that while many papers discuss the effect of the operation on the frequency of colds and sore throats, they do not discuss the effect on their severity. It might well be that careful investigation would show that while the frequency of colds is not affected by tonsillectomy, their severity is reduced. There is no evidence of this at present.

(5) *Nephritis.*—It is possible that once acute nephritis has developed the disease pursues its course irrespective of the removal of the source of infection. Addis (1931) inclined to this view, and quoted the experiment of E. C. Dickson, who caused acute nephritis in rabbits and guinea-pigs by giving them one injection of a uranium salt. The inflammatory reaction set up persisted long after all possible traces of the uranium had disappeared, chronic nephritis resulting. It would seem reasonable to suppose, however, that the prevention of exacerbations is desirable, and we know that exacerbations often follow a hæmolytic streptococcal infection. Such infections might well be prevented by prophylactic chemotherapy, as they are in rheumatic subjects, and there is no evidence that tonsillectomy will achieve more than prophylactic chemotherapy. If this failed to prevent infections, tonsillectomy would have to be considered, but the danger of tonsillectomy is the frequency with which it causes exacerbations of the nephritis. The writer (Illingworth, 1939*b*) found that the operation caused an exacerbation in 28 out of 119 nephritic children (24%) submitted to the operation, in one case causing death. It seems reasonable to suppose that such exacerbations are harmful to the child, for it is likely that they lead to a further destruction of kidney tissue. It would be interesting to determine whether chemotherapy or antihistamine drugs as a cover to tonsillectomy would prevent these exacerbations. In the present state of our knowledge one has to balance the risk of an exacerbation with the possible advantage of the operation. The trouble is that we do not know whether the complete removal of

tonsils, in which a hæmolytic streptococcal infection has been found, will do anything to cure the disease. We can certainly say that, as yet, there is no evidence that tonsillectomy has proved to be of any value in nephritis.

Much the same argument applies to rheumatic fever.

(6) *Complications of the operation.*—Complications following the operation are relatively infrequent, considering the enormous numbers of tonsillectomies, but far from rare. They tend to be seen much more by the physician than by the Ear, Nose and Throat Specialist. The Registrar-General's Returns (Glover, 1938) show at least 85 deaths each year from the operation under the age of 15. It is thought that this is an underestimate of the true position, because deaths are liable to be entered under such diagnoses as pneumonia, whereas really they are due to the operation. No purpose would be served by enumerating the various complications. The columns of the "Index Medicus" list numerous articles on the subject of complications of tonsillectomy, affecting almost every tissue in the body. Many of these complications are due, no doubt, to the bacteriæmia which so frequently follows the operation. Elliott (1939) found a bacteriæmia in 38 out of 100 children a few minutes after the operation. The organisms found included *Streptococcus pyogenes*, *Streptococcus viridans*, *Streptococcus pneumoniæ*, *Hæmophilus influenzæ*, *staphylococci* and *corynebacterium*.

There have been numerous articles concerning the danger of poliomyelitis after the operation. The evidence of that danger appears to be very strong. Aycock (quoted by Burnet, 1946) went so far as to say that the only known prophylactic measure to adopt in an outbreak of poliomyelitis is to stop all operations on tonsils and adenoids. The American National Foundation for Infantile Paralysis advised that no operation on the nose and throat should be performed during an epidemic of poliomyelitis (Editorial, *J. Pediatrics*, 1949). Magnus and Melnick (1948) showed that certain types of monkey investigated by them were rendered very much more susceptible to experimental poliomyelitis by tonsillectomy. Anderson (1945) compared the incidence of poliomyelitis following tonsillectomy before, during and after an epidemic of that infection. Before the epidemic began the poliomyelitis : tonsillectomy ratio was 0·7 : 1,000; at the height of the epidemic it was 25·5 : 1,000. Fischer and Marks (1941), Aycock (1942), and others noted the same connexion. Anderson (1945) showed that in Utah in 1943, 43% of cases of bulbar poliomyelitis were preceded by a tonsillectomy within thirty days of the onset. The incidence of poliomyelitis in those who had recently had the operation was 2·6 times more than that of the rest of the child population, while the incidence of bulbar poliomyelitis was 16 times greater than that of the rest of the child population. Cunning's evidence (1948) to the contrary, based on a questionnaire, is fallacious, because by that time the operation was not being performed in areas where the infection was prevalent.

Another striking and disturbing fact is the frequency with which the operation causes in some children a disease which, in others, it is intended to cure, or is followed by an increased frequency of that disease. Many have commented upon the frequency with which sinus infection follows the operation (Helmholz, 1930; Selkirk and Mitchell, 1931; Walker, 1947; Griffiths, 1937). The same workers found that infection of the sinuses was commoner in those who had had a tonsillectomy than in those whose tonsils were intact. The occurrence of otitis media after the operation is well known.

Kaiser (1948) found that although colds and otitis media occurred less frequently in the children who had a tonsillectomy, in the first three years after the operation, than in controls whose tonsils were intact, they occurred more frequently than in controls in the remaining part of the ten-year follow-up period. The writer (Illingworth, 1939*a*) in an investigation of 300 children with very frequent colds (averaging one per month) in the Outpatient Department of the Hospital for Sick Children, Great Ormond Street, found that the third commonest factor from which the colds originated was the operation on tonsils and adenoids. Many other workers have found a greater incidence of infections of the upper respiratory tract in those who have had the tonsils removed than in those whose tonsils are intact (Paton, 1928, 1943; Epstein, 1937; Selkirk and Mitchell, 1931; Forsythe, 1928; Glover and Wilson, 1932; Cunningham, 1931). Some of the difficulties, however, of assessing such studies have been discussed above.

In an investigation of nephritis in children (Illingworth, 1939*b*), the writer found that 18 (5%) of 365 cases of nephritis immediately followed, and were therefore presumably initiated by the operation. As already stated, the operation during the course of the nephritis caused an exacerbation in 28 out of 119 children (24%).

The psychological effect of the operation was discussed by Levy (1945). Night terrors were the characteristic response in children under 3, and negativism and fears of the dark, or of strange men, in children over 4. He thought that these responses were due largely to separation from the mother, and to the difficulty of explaining to the child what was going to happen to him.

Much more could be said about the complications of tonsillectomy, which are familiar to all physicians. Some of these are so serious that it behoves everyone to bear them in mind when considering the advisability of performing the operation in the presence of uncertain indications. The worst of these—death under the anæsthetic or from post-operative complication, is a terrible disaster which a man who has caused the operation to be performed without adequate indication, should never forget for the rest of his life. Most of us have seen such a death in children on whom the operation was done without any adequate reason.

False Indications and Contra-indications

(1) *The appearance of the tonsil.*—The most valuable contribution to the tonsil and adenoid problem in recent years is the work of Epstein (1937) at the Children's Memorial Hospital, Chicago. He attempted to correlate the careful observations of the physicians and throat surgeons in 152 children with the histological findings. He was unable to find any connexion between the severity of the symptoms and the degree of infection revealed by histology. "Some well-nourished children with no complaints save mouth-breathing had tonsils riddled with abscesses and sealed off by scar tissue. On the other hand some of the children complaining of almost constant sore throats had almost normal tonsils on histology." There was no relation between the size of the tonsil and the success of the operation in relief of symptoms. It was impossible to relate pathological evidence of infection with a history of preceding sore throats or other infections of the upper respiratory tract, neither could it be related to the prognosis. There was no connexion between redness of the anterior pillars and the degree of infection found. In some badly infected tonsils the anterior pillars were pale: some children had reddening of the anterior pillars, while their tonsils proved to be normal. He admitted that the tonsil with crypts, especially when much epithelial debris can be expressed, is usually infected. He concluded: "The physician does not know an infected tonsil when he sees one. There is nothing to lead one to feel that the appearance of the tonsils should ever influence one's judgment on the advisability of removing them. In children at least it would have a salubrious effect on the physician's attitude if he abandoned the diseased and hypertrophied tonsils and adenoids and substituted frequent sore throats or whatever the complaint or indication is. Whether tonsils were buried, cryptic, smooth, large or small bore no relation to the preoperative symptoms or the degree of success of the operation."

Many others feel that the appearance of the tonsil should not influence one's decision concerning the desirability of its removal (e.g. Denzer and Felshin, 1943; Brennemann, 1925; Dean, 1934). Most will agree that the mere size of the tonsil is no indication for the operation, except in the very rare cases in which the tonsils are so enormous that they may cause obstruction of respiration. It is normal for tonsils to enlarge at the age of 4 to 6, when immunity to infection is developing. There is some evidence of a connexion between the size of the tonsil and body build (Neuber, 1932), the large child tending to have larger tonsils than the smaller child. It is well recognized that large tonsils are not necessarily the most heavily infected ones. Caylor and Dick (1922) showed that the tonsils with the largest bacterial count per unit were the relatively small ones with chronic inflammatory changes.

Others think that the ability to express pus from the tonsil is a valuable indication for operation. More often than not, however, it is not pus which is expressed, but epithelial debris. The expression of either is often prevented by obstructing fibrous tissue.

It may be added that there is little agreement among pathologists as to what are the criteria of infection in the tonsil (Epstein, 1937; Wilkinson, 1929). Jackson and Coates (1929) concluded that: "Abscesses and abscessed crypts are present in varying numbers and sizes in all of the laryngopharyngeal lymphoid structures in the vast majority of human subjects beyond infancy—in other words a practically universal condition."

(2) *The recommendation of all and sundry.*—The decision as to the removal of tonsils should not rest with the school nurse, the mother, the father, aunt, neighbour or other lay person. Neither should the General Practitioner make the decision. He may know a lot about the child, but the decision must rest with the specialist. Neither should the pædiatrician push the throat specialist into removing the tonsils: rather he should state his opinion and ask for the opinion of his surgical colleague. No pædiatrician really respects the throat specialist who never has an opinion, who will not stand by his convictions, and who always does what he is asked to do for fear of causing offence. Some ear, nose and throat specialists have allowed themselves to become mere technicians, and to degenerate to the level of the fourth class general surgeon who first sees the acute abdomen on the operating table, instead of being consultants whose opinion is sought and respected, because it is known that they will give a carefully considered honest opinion after a full and thorough examination of the patient.

Some surgeons forget to put the child first. The child matters a very great deal more than the wishes of the doctor, nurse, mother or father. It is the child who suffers the discomfort of the operation and who may have to suffer complications of the operation. If a proper unhurried consultation is given in the out-patient department, and the problem is fully discussed with the parents, and their questions and fears are properly answered, it will be found that very few parents still want the operation to be performed when the consultant advises against it. No amount of insistence by the doctor or anyone else should ever make a surgeon perform an unnecessary operation on a patient.

(3) *Age.*—Tonsils should practically never be removed before the age of 4, and rarely before the age of 5 or 6. Adenoids should be removed for proper indications at any age.

(4) *General diseases.*—In the present state of our knowledge there is no justification for removing tonsils for any general disease unless they are producing local symptoms. They should not be removed for frequent colds, upper respiratory tract infections, or allergic conditions.

(5) *Absence of symptoms.*—They should never be removed in a child who is free from symptoms.

Suggested Indications

(1) The operation should only be recommended by a physician or surgeon if he would have it done on himself, under the same circumstances, or on his own child, due regard being paid to the possible risks of the operation.

(2) Tonsils should be removed on account of frequent tonsillitis with fever—three or four attacks a year.

(3) Tonsils should probably be removed after a peritonsillar abscess.

(4) Tonsils should be removed in the very rare case in which they are so large that they cause obstruction to respiration.

(5) Tonsils should probably be removed in diphtheria carriers in whom other treatment has failed.

(6) Adenoids should be removed when they are causing obstruction to the Eustachian tube, or are causing mouth-breathing, or are preventing the drainage of secretions, at whatever age the trouble occurs.

The writer cannot express an opinion as to whether the tonsils should be removed at the same time as the adenoids, or whether adenoids should necessarily be removed when tonsillectomy is performed.

Final Suggestions

If the operation is to be performed, it is suggested that :

(1) It should be done at a suitable time of the year.

(2) It should only be done when the child is an in-patient, never as an out-patient.

(3) The child, if old enough, should be told about the sensations he is going to experience.

(4) He should be given full premedication, so that he does not experience the unpleasantness and frightening experience of an anæsthetic.

(5) The operation should be done by dissection.

(6) The child should have proper convalescent treatment.

(7) He should be properly followed up so as to ensure that the infection for which the operation was performed has been eliminated.

THE TONSIL PROBLEM (*Abridged*)

History.—Removal of the tonsils was mentioned first in the literature by Celsus [1] in the year A.D. 10. He speaks with some familiarity of the operation and describes complete removal. In more modern times Physick [2] of Philadelphia was the first to stress the importance of complete removal of the tonsils and he introduced the first tonsillotome or guillotine. As Scott Stevenson [3] has said the rise in incidence of this operation has been one of the major phenomena of twentieth century surgery. The realization of some of the benefits to be obtained from some of the operations in suitable cases led to a wave of over-enthusiasm for operation. This is an easy operation—to do badly ; and therefore all and sundry have been attempting it. There may indeed be difficulties attending the operation and there may be serious complications, and the realization of these points should emphasize the desirability of entrusting the selection and operation of these children to properly trained laryngological teams.

Basic assumptions.—It is suggested that four basic assumptions be accepted :

(1) Where removal of tonsils and adenoids is indicated this should be complete. The technique employed is immaterial provided that results conform with this dictum.

(2) It is extremely doubtful that there is an internal secretion for these particular pieces of lymphoid tissue, any more than for Peyer's patches to be found in the intestine.

(3) It is a reasonable hypothesis that the tonsils and adenoids are part of a defensive mechanism against infection, specially highly developed at the entrance to the food and air passages and specially active when most needed. For example the enlargement of this tissue in response to local sepsis at various ages is well known; the literature is voluminous.

(4) The defence mechanism may itself become heavily infected and therefore cease to function.

Repeated upper respiratory infections are probably a function of overcrowding in home and school life. The fact that so many children are sent up about their tonsils and adenoids is surely the biggest single argument that we must expect to continue to do a large number of these operations. The tonsil problem, then, resolves itself into a double challenge—to the experts of preventive medicine, and to hospital authorities to provide an adequate number of beds.

Diagnosis.—The problem presenting itself to the laryngologist is whether the tonsils of any given child are harmful rather than valuable. Inspection alone is almost valueless because tonsils will show changes in size and appearance according to the season of the year, and according to how recently the child may have had an upper respiratory infection. The history is of paramount importance, and should be obtained from the parent and the family doctor. The school doctor is less likely to give reliable evidence because he sees the child only at routine inspection, and may not have had a chance to obtain the history from the parents, and almost certainly does not treat the child when ill. Furthermore it is important in evaluating the history to distinguish clearly between the symptoms which might be ascribable to the tonsils and those which might be ascribable to the adenoid tissue. The fact that tonsils and adenoids are frequently removed at the same sitting has led to a good deal of loose thinking and writing, and surveys of results of operation have often been clouded by the fact that the benefits or the reverse have not been ascribed to one piece of tissue rather than the other.

Assessment of adenoidal hypertrophy and infection.

Enquiries here should be directed towards the history of nasal trouble, obstruction, mouth-breathing and snoring. As a result of these questions one may discover that the child is suffering to some degree from sinus infection, and one must not be too sanguine in expecting miraculous cures of this condition by removal of the lymphoid tissue alone. Inspection should include examination of the anterior nares, and for this an aural speculum is found to be extremely useful in small children. Posterior rhinoscopy by means of a mirror is sometimes unsatisfactory, and it is suggested that more use should be made of the naso-pharyngoscope. Digital examination of the post-nasal space in children should be reserved for those cases where there has been a previous adenoidectomy and where there is doubt about residual tissue. Even then that examination is best conducted under general anæsthesia. A high-arched palate, a deviated nasal septum and dental overcrowding form a triad of signs which one should regard as important.

Assessment of the tonsils.

It has been laid down by eminent laryngologists many times that the most certain proof of chronic infection is the occurrence of repeated acute attacks. A peritonsillar abscess (even one) is an indication that the tonsil function has broken down. As has been said the appearance of the tonsils constitutes no clear evidence about whether they should be removed. On the other hand chronic enlargement of glands at the angle of the jaw would suggest that the first line of defence has in fact broken down. Unfortunately the matter cannot be settled by biopsy because morbid histologists are unable to assess the grade to which a tonsil is infected.

Five absolute indications for removal are suggested:

(1) Repeated attacks of acute infection, i.e. more than two.

(2) The occurrence of a single quinsy, though this is uncommon in children.

(3) Cervical glands persistently enlarged in the absence of chronic nasal sinus disease.

(4) Gross hypertrophy causing such obstruction to the air and food passages as to produce symptoms.

(5) Tuberculous adenitis.

In amplification of this last, it would seem a reasonable assumption that in the majority of cases of tuberculous glands in the neck the infective organism enters via the tonsil tissue. In a very large number of cases, tuberculous giant-cell systems can be found in the tonsils of such children. Irwin Moore [4], Scarff and Whitby [5] and Pagel [8] have all written about this topic. Where operation on the glands is proposed it is suggested that this should be carried out before the tonsillectomy, because minor post-operative sepsis of the tonsil-bed may lead to a secondary infection of the gland with breaking down and consequent abscess formation.

In addition, there may be relative indications for the removal of tonsils and adenoids, each of which taken singly would have no real significance. Here again the history is of some

importance. Minor sore throats, attacks of unexplained pyrexia, poor appetite, a dry "tickly" cough having no origin in the chest or nasal sinuses, repeated earache and in general such conditions as are supposedly caused by a focus of infection should all be considered on their merits. The laryngologist, however, would be wise to place major diagnostic reliance upon an actual history of repeated sore throats.

Statistical evidence.—Many statistical surveys have been made in an attempt to assess the value of this operation in children. That made by Kaiser [6] and that by Paton [7] may be mentioned. These surveys are open to criticism from one standpoint or another. For instance it would seem to be important to compare the history of children who have their tonsils and adenoids removed before and after the operation, rather than compare those children with another series who were supposedly healthy. Advice from a statistical expert on this matter suggested that children presenting themselves in the clinic should be divided into two main groups, those who needed the operation and those who did not. Half of the number in each group should have their tonsils and adenoids removed and the other half should be spared the operation. The subsequent history of each sub-group should then be compared with its own prior history, and with the subsequent history of each other sub-group.

It is evident that it would be difficult to reconcile such a survey with clinical honesty.

A brief survey of 337 children upon whom the dual operation was performed in the Radcliffe Infirmary in the last two years has been made by Miss Esmé Hadfield, and her results, though probably not satisfactory to the statistician, at least embody the principle that the children are compared with themselves. It is suggested that no other comparisons are so valid when dealing with methods of treatment of disease in the human subject.

Poliomyelitis and tonsillectomy.—It is generally agreed that the virus of poliomyelitis can be transmitted either by droplet spray or by the intestinal route, and that the latter is the more important. It is suggested that the virus settles in the tonsillar fossæ in recently operated patients and travels straight up the nerve sheath so exposed to the brain. Evidence has been collected that where cases of poliomyelitis closely follow upon tonsillectomy, the type of case is likely to be bulbar rather than spinal. The small number of very dramatic family groups where something of this kind has occurred lend colour to the idea. But it must be remembered that there is no proof that these children had acquired the infection *de novo*, that they were about to develop the disease anyway, or that they were in fact carriers.

Very little can be said with certainty about the epidemiology of this disease, and though it is supposed that the invasion and carrier rates in the child population are very high in the season of peak incidence, it may also be concluded that the immunity rate is high, too.

Scott Stevenson [3] has made a survey of the figures reaching this country from the United States of America and these have been extremely contradictory. In general it seems that the incidence-rate of poliomyelitis in recently tonsillectomized children is about the same as it is in the total child population, but that where such cases do occur they tend to be bulbar and therefore severe. It is necessary to preserve a sense of proportion in this matter, and to remember that the risk of a given child contracting poliomyelitis within a given period of time is less than the risk it runs in crossing a city street. It is suggested that from a public health point of view it is important to weigh that chance against the total good done to the child population by well-chosen operations in the optimum season.

Extra beds.—The waiting list for cases of tonsils and adenoids is something quite distinct from the general list of ear, nose and throat cases. This is, it is suggested, the true "Tonsil Problem". The introduction of the Health Service will, it is hoped, be followed by a very proper diminution of the number of unskilled operations and of the use to which Cottage hospitals are put for this purpose.

Conclusions

(1) Removal of the tonsils has been known as a beneficial operation for 2,000 years at least.

(2) The hypertrophy of the lymphoid tissue calling for operation is due to repeated infections; these being determined by the overcrowded conditions of civilized life.

(3) The number of children continuing to be sent up by their family doctors is in itself the best argument that in selected cases the operation is a beneficial procedure.

(4) The diagnostic criteria now adopted by responsible laryngologists are conservative and sound. Adenoids need separate consideration from tonsils.

(5) The selection of the cases and the operation should be in the hands of specialist teams.

(6) There is a nation-wide shortage of beds, but hospitals could devote beds to no better purpose.

(7) There is no satisfactorily established evidence that the removal of tonsils and adenoids increases the likelihood of a patient acquiring an infection with the virus of poliomyelitis in the epidemic season.

Miss Esmé H. Hadfield: This pilot survey was made at very short notice and I doubt if the figures are statistically significant although I believe them to be mathematically correct. Altogether 337 children were reviewed. Of these 170 had had their tonsils and adenoids removed in 1947 and 167 in 1948. The cases were in no way selected, and although I have not worked out the age and sex distribution accurately I believe that they are roughly equal in each group. The family doctors of these children were circularized and asked for their comments on their health since operation. Some of their answers were very full and helpful, but the proportion who had lost touch with the children was too high to make it worth while to analyse their statements.

One was very impressed in making the survey by the mothers' answers to the question "is this child better or not for the operation?" Such remarks as "100% better", "a different child", and "she lived on M & B before" occurred with gratifying frequency. However, one was prevented from becoming too smug by the rare mother who produced a long tale of illness which began the moment that the child returned home from the hospital and was still going on.

While reviewing these children I picked up 4 who needed investigation of their sinuses, 3 with allergic rhinitis, 4 with tonsil relics who were still getting severe sore throats, 1 with chronic otitis media, and 10 with unrelated pathological conditions.

My first table shows the percentage answers to the question: "Is the child better or not for the operation?"

	Better	Not better	Don't know	Unchanged
1947	89·4	1·2	4·7	4·7
1948	88·6	1·2	6·6	3·6

Incidence of sore throats before and after the operation.

	Sore throat before none since	Never had a sore throat	Still has sore throat
1947	58·0	30·0	12·0
1948	68·0	23·5	8·5

Incidence of colds.

	More colds	Less colds	Unchanged	Don't know
1947	3·5	74·0	22·0	0·5
1948	0·6	90·0	9·4	0

Improvement or not in hearing. (Of course in the large proportion of children the hearing had never been affected.)

	Better	Worse	Not better	Never affected
1947	15·6	4·3	3·0	77·1
1948	17·0	0·6	4·2	78·2

Snoring.

	Before operation but not since	Never snored	Still snoring
1947	73·0	16·8	10·2
1948	75·0	21·5	3·5

Incidence of aural discharge without symptoms of acute otitis media.

	Before but not since	Since but not before	Before and since	Never
1947	10·6	3·0	5·9	80·5
1948	13·2	0·6	3·0	83·2

Incidence of acute otitis media.

	Before not since	Since but not before	Before and since	Never
1947	8·3	5·3	2·3	84·1
1948	7·6	0·6	1·8	90·0

Present general condition and development of the children.

	Average	Above average	Below average
1947	55·0	28·2	16·8
1948	62·7	26·5	10·8

Only one child had had a subsequent operation on the ears, nose or throat and this child had had a re-adenoidectomy.

Mr. R. Scott Stevenson said that he must take exception to Professor Illingworth's use of the word "irrefutable" regarding the alleged evil influence of tonsillectomy on the incidence of poliomyelitis. The evidence from America, on which this opinion was founded (for there was not enough evidence in this country), was certainly not "irrefutable". For his own part he thought it wrong to found an opinion one way or another on the American evidence, for one publication was cancelled out by another ; if Professor Illingworth quoted Utah in 1943 he could quote against him Wichita, Kansas, in 1940, and so on and on ; there were scores of articles to quote from on each side.

Probably the most reliable authority in this field was D. S. Cunning of New York, who, in recent years, had been collecting statistics from different districts and analysing them in the form of a useful annual report. Cunning (*Laryngoscope*, 1949, **59**, 441), who had studied 17,000 cases of poliomyelitis and 35,000 cases of tonsillectomy, said that he was "quite convinced that no definite causal relationship between tonsillectomy and poliomyelitis had been established". In the Manhattan Eye, Ear and Throat Hospital, among 35,039 children in nine recent years who had had their tonsils operated on, only 5 had contracted bulbar poliomyelitis.

Turning to the subject of tonsillectomy, the attack upon that operation in recent years was in the main by public health officials and had been grossly exaggerated. The Medical Research Council in a report on epidemics in schools in 1938 stated that "there was a tendency for the operation to be performed as a routine prophylactic ritual for no particular reason and with no particular result". Such a remark was merely an impertinence and unworthy of an M.R.C. publication. Dr. Alison Glover's repeated attacks on tonsillectomy were more worthy of attention, but his opinions had been founded entirely on statistic and they all knew what they could do with statistics.

Professor Illingworth was good enough to say that the ear, nose and throat specialist was a better judge than the pædiatrician on whether tonsillectomy should be done or not. He himself felt that the problem was best approached from the point of view of the patient's history, and the child's mother might often make the best judge. Was the child getting sore throats, frequent colds, otitis media ? If the tonsils were giving trouble they should be taken out ; but if they were not giving trouble they should be left alone.

The following speakers also took part in the subsequent discussion : **The President (Mr. R. D. Owen), Mr. H. V. Forster, Mr. Mackenzie Ross, Dr. R. F. Hendtlass, Dr. J. C. McFarland, Mr. W. L. Thomas, Mr. T. A. Clarke, Mr. Munroe Black, Mr. Denis Browne.**

Professor Illingworth, in reply, said how much he had enjoyed Mr. Scott Stevenson's contribution. Mr. Scott Stevenson had stated that Cunning was the most reliable worker in the United States. That was a statement which he could not accept. Mr. Scott Stevenson had further said that he did not believe at all in statistics, and then he had gone on to try to convert them with statistics from Cunning. He himself knew the work of Cunning and had read his articles, but he felt that there were snags in that statistical study. One was that in the questionnaire which was sent out at the instigation of the American Oto-Rhino-Laryngological Society, the results were obtained after the operation had been very largely stopped in the areas where poliomyelitis was most heavily epidemic ; therefore the results were rather obscure. In the areas where there was poliomyelitis a lot of people decided not to do the operation. The American Foundation for Infantile Paralysis recommended that the operation should not be done during the prevalence of a poliomyelitis outbreak.

Section of Neurology

President—JULIAN TAYLOR, C.B.E., M.S., F.R.C.S., F.R.A.C.S.

[*December* 1, 1949]

DISCUSSION ON CURRENT TRENDS IN THE MANAGEMENT OF THE GLIOMATA

Mr. Joe Pennybacker (The Nuffield Department of Surgery, Radcliffe Infirmary, Oxford): As so much of neurosurgical interest in the past ten years has been centred on head injuries, infections, and psychosurgery, I thought it would be salutary to consider a group of cases which comprises nearly half of all intracranial tumours, a group which remains, after more than a quarter of a century of rapid advances in technique, a most troublesome problem for the neurologist, physician and surgeon alike. My survey has been somewhat depressing, how depressing will be apparent as my report unfolds. Our material consists of 716 cases of verified gliomata of the brain dealt with in the Nuffield Department of Surgery in Oxford during the past eleven years.

TABLE I.—INTRACRANIAL GLIOMATA

Cerebellar astrocytoma ..	44	8·52%	
Ependymoma..	17		16·5%
(Cerebellar 10)			
(Cerebral 7)			
Medulloblastoma	57		
Spongioblastoma multiforme	282		39%
Astrocytoma (cerebral) ..	181		
Oligodendroglioma	44		44%
Unclassified	91		
Total	716		

In Table I it will be seen that only just under 9% of these tumours are reasonably benign—these are the cerebellar astrocytomas and ependymomas. If a *cerebellar astrocytoma*, the common tumour of childhood, be completely removed it does not recur and many of our early cases are still alive and well. Much longer survival periods are common but in the present series there are two cases of recurrences eleven and twelve years after a primary removal. This raises the question as to how often complete removal is possible: certainly it is not possible if the tumour extends into the brain-stem, and this occurred in no less than 11 of our 44 cases, i.e. in 25%. But there is every reason for pursuing a cerebellar astrocytoma with the utmost vigour. If an irremovable extension is found, there may still be a long period of useful survival and in one case there has been good evidence of response to radiation therapy.

I have been a little disappointed to find that it is not uncommon for children who have had complete removals done in early childhood to grow up with slight mental defects or behaviour disorders which may lead to difficulties in social adjustment. This may be the result of the long-standing hydrocephalus which usually exists in these cases before they come for treatment. The defect is rarely serious but it may mar what is otherwise a complete recovery.

Two technical matters are worth mentioning. The first is that in the case of infants and small children it is safer to remove the tumour in two stages rather than at one session. At the first operation a decompression is done, the tumour is verified, and if there is a cyst present it is tapped. We then prefer to wait for three to four months to allow an adjustment to the altered pressure relationships afforded by the decompression. At the second operation, the tumour can be taken out with a good deal more safety and less post-operative worry than if the whole procedure had been done in one stage.

The second point is that all of these lesions causing hydrocephalus should be verified if at all possible. There is a current vogue for easy short-circuiting procedures such as ventriculocisternostomy and ventriculostomy for hydrocephalus, and remediable lesions may be missed if care is not taken to be certain just what is causing the hydrocephalus.

Fig. 1 shows the ventriculogram in a boy of 16 who had had periodic occipital headache for seven years, and some unsteadiness of gait for one year. On examination in October 1940 there was some enlargement of the skull, bilateral papilloedema, no nystagmus, and slight generalized unsteadiness of his limbs. The ventriculogram (A–B, Fig. 1) we interpreted as indicating hydrocephalus due to stenosis of the aqueduct, as only the upper part of the aqueduct could be filled and it ended in a sharp point as is commonly seen in this condition. We made an anterior ventriculostomy (incision of the lamina terminalis) and this seemed to be effective as the headache ceased and the papilloedema subsided. But there was little improvement in the neurological status and because of this he was readmitted ten months later and the ventriculogram was repeated. The ventricles (C–D, Fig. 1) were smaller and an air shadow could be seen at the site of the fistula indicating that it was effective. The posterior end of the third ventricle was deformed and we then thought that the lesion had all along been a brain-stem tumour which was now growing up into the third ventricle. He died suddenly two months later and at autopsy there was a large cystic and solid astrocytoma of the vermis. Had we even inspected the posterior fossa in this case, the result might have been different.

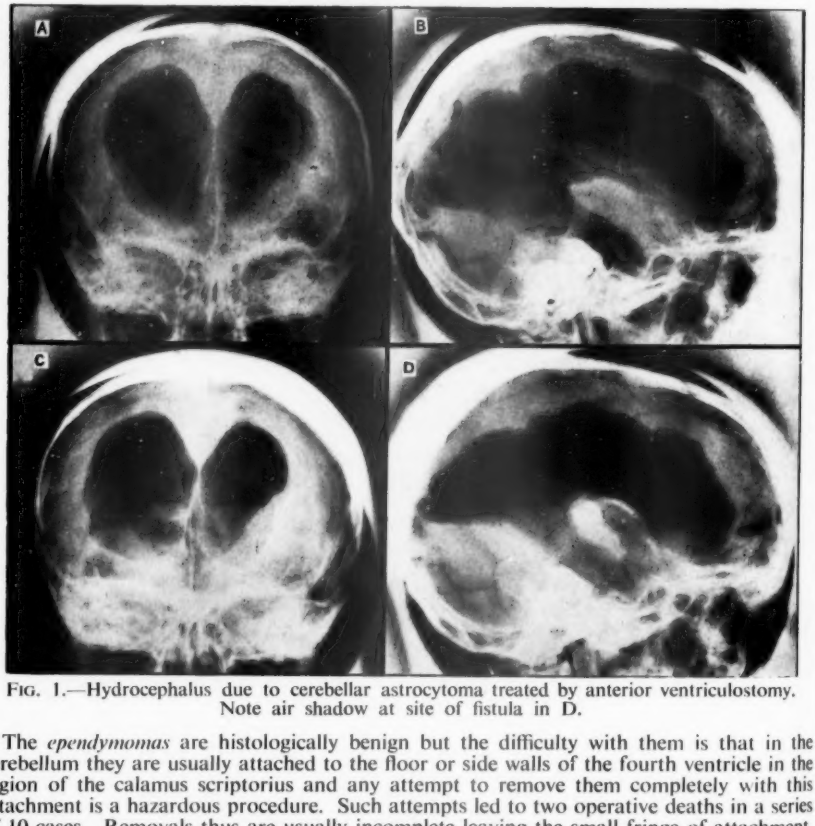

FIG. 1.—Hydrocephalus due to cerebellar astrocytoma treated by anterior ventriculostomy. Note air shadow at site of fistula in D.

The *ependymomas* are histologically benign but the difficulty with them is that in the cerebellum they are usually attached to the floor or side walls of the fourth ventricle in the region of the calamus scriptorius and any attempt to remove them completely with this attachment is a hazardous procedure. Such attempts led to two operative deaths in a series of 10 cases. Removals thus are usually incomplete leaving the small fringe of attachment, but I think we have good evidence that these tumours are radio-sensitive, and that it should be possible to deal with this remnant by radiation therapy after as complete a removal as is deemed safe.

Thus in November 1939 we admitted a child of 7 who, for five weeks, had had severe headache and vomiting culminating in stupor. On examination, she was drowsy, incontinent and wasted. There was bilateral papilloedema of 3D., a little nystagmus on looking to each side, hypotonia and unsteadiness of all her limbs. In addition she complained of acute pain in the right hip and held it in an attitude of flexion and adduction, resisting any attempt at passive movement. X-rays of the skull, spine and hips were normal. We thought that this was probably a medulloblastoma with spinal metastases, and in the rush of work at that time did not verify the lesion or provide a decompression but sent the patient off for a course of radiation treatment. There was a prompt and dramatic response and when she was seen in March 1940 she looked and felt well and there were no detectable abnormalities on examination. She remained well for one year, but in March 1941 there was a recurrence of headache and papilloedema, and she had another course of treatment. Again there was a good response, and she remained free from symptoms and signs for two and a half years.

Again there was a recurrence, but a third course of treatment brought about no improvement and she died in December 1943, four years after the onset of symptoms. At necropsy, the tumour was found to be an ependymoma of the fourth ventricle.

The improvement in this case must be attributed to the radiation therapy as there was no decompression and the skull did not expand by separation of the sutures, a mechanism which often provides temporary relief of pressure symptoms in childhood.

Of the cases verified at operation, one removed in 1939 followed by X-ray therapy has remained well up to the present time. Another removed in 1938 had a recurrence ten years later which was verified at a second operation and then had X-ray treatment with a satisfactory remission of symptoms. Another removed in May 1945 had a recurrence of symptoms nine months later, but a course of X-ray therapy brought about a prompt improvement and she has remained well since then.

In the cerebral hemispheres, the ependymomas have no constant situation and they behave much as any other intrinsic neoplasm. There is thus not the same risk at radical removal as in the cerebellum, but as they are often very large and complete removal cannot be assured we have usually followed operation with X-ray therapy. One case with complete removal in 1941 followed by radiation has shown no evidence of recurrence up to the present time. Another case treated by a bony decompression and X-rays in 1940 remained free from symptoms for five and a half years.

Thus we feel that the proper management of these tumours entails as complete removal as is considered safe followed by a course of radiation therapy.

The *medulloblastomata* comprised about half of the cerebellar tumours, the vast majority of them occurring in childhood or adolescence. And in this series the picture was one of almost unmitigated gloom. When Cushing and Bailey gave these tumours a separate identity the average survival period was about seven months after operation. With the recognition of their radio-sensitivity, and improvements in radiation technique, the average survival period began to lengthen to eighteen months or two years and practically all of our cases succumbed within this time. All which survived operation had radiation treatment, and it has apparently made little difference to the ultimate survival whether an extensive removal has been done or not. I should say, however, that in considering the immediate operative mortality, it seems to be more dangerous to remove too little than too much and we now think that a very radical removal should be attempted if at all possible. This can be more easily done by excising the vermis and the adjacent parts of both cerebellar lobes rather than relying on the mid-line vermis incision which Cushing introduced. But in my view the solution of this problem does not lie with the surgeon. Lampe and MacIntyre (1949) in a recent survey state that surgery has never cured a medulloblastoma: they were unable to find a verified case which survived more than three years when sole reliance had been placed on surgical removal, i.e. without radiation. Spitz, Shenkin and Grant (1947) in an analysis of 97 cases found that of 60 patients under the age of 16 years, none survived longer than three and a half years with surgery and radiation. But these authors call attention to the fact that when a medulloblastoma occurs in adult life the outlook may be a good deal better: among 21 patients with adequate follow-up data, 13 survived three or more years after operation, 9 for four years or more, 4 for five years or more; 3 patients were still alive three, six and eight years after operation. In about half of these cases the tumour was in the lateral lobe of the cerebellum rather than in the vermis. Penfield and Feindel (1947) reported one case of a woman of 22 with a medulloblastoma of the lateral lobe of the cerebellum which was removed in December 1928, and a course of deep X-ray therapy was given after operation. The patient remained well for nine years, when a recurrence of headache and papillœdema led to another cerebellar exploration at which no tumour was found and it was presumed that there was another tumour in some other part of the brain. A second course of radiation brought about a complete recovery for another seven years, when a recurrence of symptoms led to a third course of radiation. The response was less satisfactory this time and she died in October 1945, seventeen years after coming under treatment.

We have had only one example of this relatively favourable group, a man of 35 who had a medulloblastoma of the left lobe of the cerebellum removed in August 1942. A course of X-ray treatment was given after operation and he has remained well up to the present time, seven years after operation. It is thus worth approaching these tumours with somewhat more optimism than is so far justified when they occur in childhood. For the latter, which constitutes the bulk of the problem, surgery must be followed by radiotherapy, and improved techniques do hold out some promise: Lampe and MacIntyre report that although 17 of their 25 patients succumbed within 38 months, 1 lived for 68 months, and 7 (28%) survived for periods ranging from 33 to 92 months (33, 47, 50, 70, 72, 83, and 92). These are the best results that I know of with this type of tumour, and I hope they will stimulate our colleagues in radiotherapy to increase their efforts.

Turning now to the tumours of the cerebral hemispheres which account for about 80% of all gliomata, and about half of which are *spongioblastoma multiforme*.

TABLE II.—SPONGIOBLASTOMA MULTIFORME—282 CASES

Died in hospital		110
Discharged from hospital, deteriorating		83
Major interventions—number of cases		89
Operative deaths	14 (16%)	
Survivors	75	
28 "Deteriorating" in 6 months, no P.M.		
38 died within 16 months		
6 died within 18–33 months		
1 died at 48 months		
1 died at 51 months		
1 alive and well after 51 months		
Useful survivals (longest 51 months)	30	

It has been known from the early days of brain surgery that these are unfavourable tumours, but I doubt whether any of us realize quite how bad they are until we are faced with figures. We operate on these patients, they often get out of hospital, we see them at the follow-up clinic once or twice, and we forget them in the welter of new cases and of the more benign types which keep on coming up year after year. But in fact 110 of these 282 patients died in hospital. In the majority of these, death was accelerated by a ventriculogram and biopsy and in most it was a merciful release. 83 patients survived the procedures involved in verifying the lesion—and in this connexion I should say that arteriography and burr-hole biopsy seem to be a good deal less lethal than ventriculography and biopsy—but in all cases the patient was described as deteriorating on discharge from hospital and there were no useful survivals.

This leaves 89 cases in which the circumstances were such that we considered some major intervention worth while, in most cases with a view to radiation treatment subsequently. These procedures ranged from decompressions to complete removal although usually the removal was known to be incomplete and the operation really amounted to an internal decompression. There were 14 operative deaths in this group, a mortality rate of 16%. Of the 75 survivors, 38 were known to be dead within 16 months, 6 survived for periods from 18 to 33 months, one for 48 months and one for 51 months. One patient is still alive and well 51 months after removal of the tumour (*vide infra*). In all cases recurrence of the tumour seemed to be the cause of death. Of the remaining 28 cases, we have no final note of death, but in almost all of them there was evidence of deterioration within six months of operation, and it is safe to assume that they died shortly afterwards.

These figures relate to the survival period, but if we consider them from the point of *useful* survival, the aspect is even more sombre. Of course the term useful survival is somewhat arbitrary: what might be so regarded by an optimistic surgeon might be quite differently assessed by the patient's relatives, and vice versa. We have taken as a rough standard, a man's ability to return to his work, or to some wage-earning occupation, and in the case of women, the ability to return to housework, shopping, and the care of their family, &c. There is an additional factor and that is the *duration* of useful survival, and this is even more arbitrary than our definition of useful survival. It usually takes at least a month for a patient to convalesce from his surgical experiences, and even though he returns to work for a month, and then has a recurrence, it may be doubted whether this month should count as useful survival, and in my opinion it should not. I see no humanity in snatching a person from the jaws of death, his working for a month or two, and then having to undergo a fatal illness for the second time. Such cases I have discarded, and I find that of our whole material there were only 30 cases of useful survival, 18 of them survived usefully for periods up to 6 months, 3 for 9 months, 3 for 12 months, 2 for 24 months, one each for 30 and 33 months, one for 48 months, and one for 51 months.

The general trend of these figures has been apparent for several years, and to be realistic about these tumours in the present state of our hospital services, the most important thing about them is histological verification. All of us have had the experience, not once or twice but many times, of being faced with the case in which there is every reason to diagnose a rapidly growing glioma, and which at operation or autopsy proves to be a meningioma, subdural hæmatoma, abscess or the like. The differentiation cannot be made on clinical evidence, nor will electro-encephalography, ventriculography or arteriography always provide the right answer. We have seen a practitioner with an almost unique experience of arteriography mistake a spongioblastoma multiforme for a meningioma, and on the next day making the opposite mistake. The only certain way is histological verification and this means a biopsy after accurate localization by arteriography or ventriculography. In cases in which there is already profound disability such as aphasia, hemiplegia or mental derangement, and when the diagnosis of spongioblastoma multiforme is proved histologically, we think surgery has nothing to offer. Heroic operations may prolong existence for a few months, but this usually means that some other member of the family is sacrificed to look after the invalid, and the social havoc which may result from such surgery is often appalling.

The situation may be a little different in those cases in which increased intracranial pressure is the dominant factor and there is little neurological or mental deficit. Such lesions are apt to be in the frontal, parieto-occipital or minor temporal lobes, and there may be something to be said for extensive removals. In this series, the extent of the removal has not appeared to make a great deal of difference to the ultimate survival. Professor Russell and I have previously reported a case (1948), not included in this series, of a right frontal spongioblastoma multiforme, treated by decompression and several courses of radiation treatment, which survived for seven and a quarter years. In this case the amount of tumour removed was only sufficient for histological study. On the other hand, in a clinically comparable case in this series a tumour weighing 114 grammes was removed from the right frontal lobe in October 1948 with a gratifying immediate result, but headache recurred within three months, fits in six months, with death at ten months. At autopsy the large operative cavity in the fore-part of the right hemisphere had been completely replaced by tumour (Fig. 2).

FIG. 2.—Brain from which 114-gramme spongioblastoma multiforme had been removed ten months before death. Note massive recurrence.

Early diagnosis.—On general grounds it might be supposed that if we could get these tumours early enough, and remove them when they are small the outlook might be better. In this connexion I should mention 2 cases:

The first was a man of 37, who was operated on in August 1939. He had a small, apparently circumscribed glioma in the right mid-frontal cortex measuring 2·5 cm. in diameter. It was removed completely with a liberal surrounding of normal white matter, and we thought that the outlook was good, as this seemed to be a small tumour, detected early, and removed completely. This patient was dead in January 1940, five months after operation, and at the autopsy the tumour measured $9 \times 9 \times 6$ cm. and occupied both frontal lobes and the corpus callosum. He had had no X-ray treatment.

The second case is a woman of 38, who had a tumour of about the same size (3 cm. in diameter) removed from the cortex of the right parietal region in August 1945. It, too, appeared to be circumscribed, and was removed in a block of tissue measuring $6 \times 4 \times 3$ cm. She had a course of radiation after the operation and is alive and well at present, 4¼ years after operation.

These two cases stress at once the despair and the unpredictability which attend the surgery of the gliomata. They also add emphasis to a theme which has kept recurring throughout my remarks, that surgery alone is powerless in the management of many of these tumours and that the combined efforts of surgeon and radiotherapist are essential. In conclusion I would like to mention a case which we have in hospital at present:

A woman of 34, who was admitted in November 1939, with headache, vomiting, occasional epileptic attacks, papillœdema, some mental derangement and little in the way of other physical abnormalities. The ventriculogram (Fig. 3) we interpreted as bespeaking a bifrontal glioma invading the corpus callosum and septum lucidum, and inoperable. She was provided with a subtemporal decompression and had a course of X-ray treatment and remained quite well for nine years, until October 1948 when she reported with a recurrence of symptoms. The decompression was tight, she had papillœdema, stupor, &c., and a further course of treatment again brought about a dramatic response. She was again seen in October 1949, free from symptoms but in early December there was a recurrence of headache and vomiting leading to her readmission. The ventriculogram was repeated and it was essentially similar to the one ten years before. At operation, an astrocytoma weighing 128 grammes was removed from the right frontal lobe, but the tumour could be seen to be invading the corpus callosum as well.

FIG. 3.—Ventriculogram in bifrontal astrocytoma.

This result I think can only be attributed to the radiation and we have a few cases of almost all types of glioma which have seemed to respond at least for a time and to some extent. Most of us realize the limitations of surgery, and although radiotherapy alone is not sufficient, I regard the recognition of its proper role in conjunction with surgery as the most significant trend in the management of the gliomata.

Mr. D. W. C. Northfield: For my contribution to the Discussion I have chosen only a few of the commonly accepted groups of gliomata, and they come from the period of approximately 1939–1944. They include several cases from the time when Sir Hugh Cairns was at the London Hospital, patients who have since then been under my observation. I shall not deal with the cerebellar astrocytomas, the medulloblastomas, or the gliomata of the brain-stem. There are 58 cases of glioblastoma (spongioblastoma) multiforme in which a full follow-up is available. Many of these patients died in hospital without major craniotomy, although in such some diagnostic measure was usually employed in order to confirm the diagnosis. In the others an attempt was made to remove the tumour as completely as seemed compatible with useful existence, and radiotherapy was given in many. The results are such as Mr. Pennybacker has described; an occasional patient survived for over a year, in fact 4 for over two years. But one patient is still alive and deserves comment.

At operation in 1943, six years ago, the tumour—a small one in the frontal lobe—was removed with a good margin of brain. The patient received X-ray treatment and returned to work. Four years later in 1947 there were focal signs suggestive of a recurrence, but these mostly disappeared spontaneously and were presumably the result of a focus of radionecrosis. There has been no further evidence of deterioration.

The next group comprises 39 cases of cerebral astrocytoma, and in Fig. 1 is set out a graphic representation of the length of history in years before operation, and of post-operative survival. The queries denote some doubt as to the precise length of history, and the precise date of death. In 7 patients death occurred without any operation, or following biopsy by needling, and in another 7 death followed major craniotomy. In some no attempt was made to remove the tumour, in others the removal was frankly partial and therefore recognized as palliative, in a few it appeared to the naked eye that the tumour had been removed completely. The late results appear unaffected by the operative procedure. There have been a few cases of long survival; up to a maximum of seven years in a woman now dead in whom the tumour quite obviously was inoperable, but the seven years were useful years during which she became happily married. 3 patients have lived for over five years, and 6 for over four years. 2 patients are still alive, one $5\frac{3}{4}$ years after evacuating a cyst, and removing some tumour for histology; and in the other the tumour appeared macroscopically localized and was thought to be completely extirpated. This impression was given support by Dr. Greenfield's statement that microscopically the tumour had

a sharp edge. Both patients are living useful lives. Many of these tumours have a very long natural history—a point to be remembered.

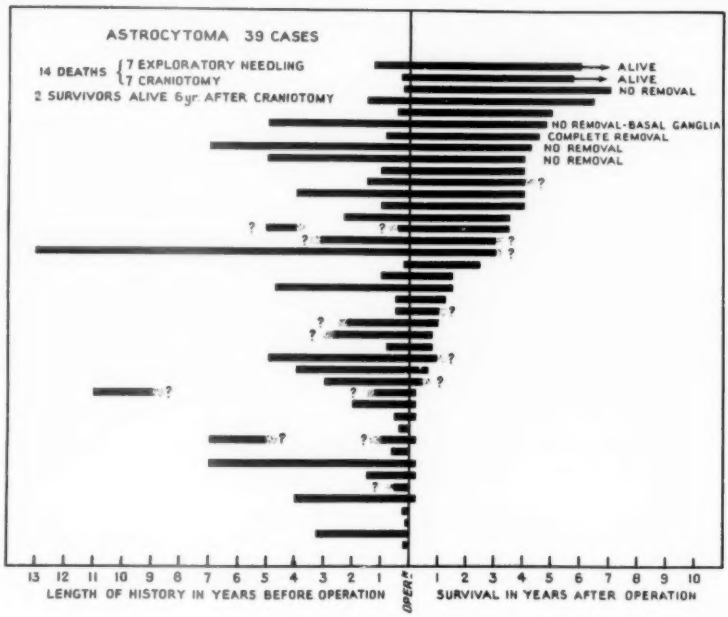

FIG. 1.

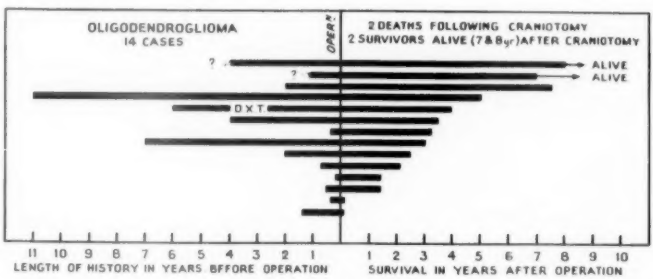

FIG. 2.

Fig. 2 deals with cases of oligodendroglioma of which there are 15 examples (14 only on the chart). All patients were subjected to craniotomy, from which 3 died, and the surviving 12 subsequently received X-ray treatment. One is still alive after what appeared to be total removal eight years ago, but he is handicapped by epilepsy; this tumour was histologically designated as rapidly growing and mitoses were seen. Another patient lives seven years after a known incomplete removal of a shaggy vascular intraventricular growth, and she is very well and has worked hard throughout this time. The patient dying 7½ years after a radical operation in 1935 by Sir Hugh Cairns, had signs of a massive recurrence and received X-ray treatment in 1938 and again in 1940 with obvious benefit on each occasion. This chart brings out a point which I think is of fundamental importance in the understanding of gliomata—their biological behaviour. The cases with long pre-operative history are usually those with long post-operative survival. The initial symptom in these long stories, as in the astrocytoma group, is usually epilepsy, and operation is an interlude demanded by the symptoms of raised intracranial pressure, or by the evolution of a neurological defect. In this connexion the following case is instructive, and is the one not charted.

A man was admitted in 1936 to the London Hospital under Sir Hugh Cairns on account of left-sided focal epilepsy of approximately a year's duration; there was a history of several head injuries, and a scar was present at the vertex in an appropriate position for the focal epilepsy to be considered

possibly post-traumatic. There was only equivocal weakness of the left limbs. X-ray of the skull showed a fleck of calcification in the right frontal lobe, and an encephalogram showed some dilatation of the right ventricle. Exploratory craniotomy revealed shrunken gyri, no biopsy was performed, and the diagnosis of post-traumatic epilepsy seemed correct. He was observed regularly, and his fits fluctuated in degree and in frequency. In 1948, that is thirteen years after the onset of fits, they became worse, and the slight weakness of the left limbs became more definite. Encephalography now revealed a typical tumour defect, and at craniotomy a massive oligodendroglioma was encountered; he died shortly afterwards.

The other group of hemisphere gliomata I wish to mention are the ependymomata. There have been only 5 in the period under review, 3 in the third ventricle, 1 in the lateral ventricle and hemisphere, and 1 in the cerebrum not apparently attached to the ventricle. The results have been bad. 2 of the third ventricle tumours died as a result of the operation; the third died of a recurrence a year after operation, at which the tumour seemed to be completely removed, as it appeared only lightly adherent to the walls of the ventricle. Of the lateral tumours, one survived a year; the other three-and-a-half years, a second attempt to remove a recurrence of the tumour which seemed completely removed at the first being equally fruitless. My experience with the fourth ventricle tumours is similar to that of Mr. Pennybacker; provided the enucleation is complete—and this endeavour may make the operation lethal—the results are as good as with the cerebellar astrocytoma.

The treatment of gliomata is a gloomy business, with the exception of certain well-defined entities, viz. the cerebellar astrocytoma and ependymoma. But there are the occasional cases which survive for long periods, whatever procedure is carried out, and these at first sight seem to confuse rather than to clarify the picture. This I believe is due to a fundamental misconception of the nature of the tumours we are dealing with. The surgeon is apt to believe when he removes apparently completely a compact mass of tumour—perhaps a so-called mural nodule in the wall of a cyst—and histologically diagnosed as an astrocytoma that he has removed a benign tumour. But surely nothing is further from the truth. Carmichael in 1928 and Scherer more recently have shown very clearly that the astrocytoma is a diffuse and infiltrating tumour, extending microscopically far beyond the confines of the macroscopically visible tumour. The use of the adjective "benign" for a glioma is a misnomer if it implies, as it should, an encapsulated tumour. Scherer divides the manner of growth of the gliomata into expansive and infiltrative; expansive growth pushes aside brain tissue with a minimum of infiltration, thus simulating a benign biological characteristic. He states that only the ependymoma has this manner of growth, and that not always. Growth by infiltration is shown by all other gliomata to varying degrees, and moreover this property does not correspond with the malignancy of the cells. The cerebral astrocytoma he considers the most invasive of all gliomata, but amongst the glioblastomata some 20% are found in which invasiveness is relatively circumscribed. The oligodendroglioma is similarly less invasive than the astrocytoma. The other important distinction which Scherer emphasizes, which we probably all appreciate but do not constantly bear in mind, is that invasion by tumour does not necessarily mean the destruction of the nervous tissue involved; invasion can occur with, and without, destruction. This is of great clinical importance in the natural history or the biology of the slow-growing astrocytoma and oligodendroglioma. Tumour may be present for many years, perhaps causing epilepsy but causing no significant neurological deficit. Such patients may ultimately need operation for the relief of raised intracranial pressure, the evacuation of cysts, and partial removal of the tumour may provide a useful internal decompression, but the surgeon cannot hope to do more.

Another problem is the varying histological picture which a tumour may present in different areas. If the surgeon receives a report that the tissue he removed is a glioblastoma, he has no assurance that the part left behind may not be predominantly astrocytoma and more slowly growing, and so his case of glioblastoma will perhaps survive for a surprisingly long time. The reverse holds true, that his patient with an astrocytoma may die in a few months, and if he has not the fortune to obtain the brain he will not learn the histology of the remaining part of the tumour which may be anaplastic.

If we examine again the chart of astrocytomata we find that some show long histories, with long post-operative survival. Others of this group show no such relation, and in others the evolution has been entirely rapid. Surely the explanation of these anomalies is that the group is not a homogeneous one, but a mixture of cases of slowly growing and of rapidly growing tumours and probably varying their invasive and destructive powers. They have different biological qualities which are not reflected in the name astrocytoma, which is attached to them.

Finally, in the surgery of the glioblastomata we have to face the possibility that in some patients, even if the tumour be removed with a good margin of healthy tissue, there may be a recurrence, not as a result of leaving behind some of the tumour, but because of the multicentric origin of some glioblastomata.

The present practice in the treatment of gliomata is, in the first place, an attempt at a pathological diagnosis. This may often be suspected from the clinical picture, and

angiography may give valuable help. Clearly when there is doubt between a glioblastoma and a meningioma, the old-fashioned method of placing greater reliance on clinical judgment than on ancillary methods will usually lead to exploration. In some cases, the circumstances will suggest biopsy by needling; in the series of glioblastomata under review this was undertaken in 40 patients, providing a positive histological diagnosis in 13, equivocal findings such as cyst fluid or a doubtful histological report in 14, and it was uninformative in 13. If a glioblastoma is diagnosed, the trend nowadays is to avoid operation, and this I believe to be correct when the tumour is invading eloquent areas of the brain. But in certain cases operation should be carried out, on humane grounds to relieve suffering where death is not imminent, and in those cases in which there is some reason to believe that a total enucleation may be possible. In these cases, more surgery and more *radicai* surgery seems the right direction in the future.

It has been shown that a glioblastoma may possess a false line of cleavage around its margin. This may be due to a narrow marginal zone of necrosis, misleading to the surgeon, who by following this plane leaves behind a thin rind of active tumour. In other cases the tumour is surrounded by gliosis, a form of capsule, which makes for easy removal of the apparently localized tumour. But on histological examination, tumour cells will be found permeating the white matter beyond the zone of gliosis. Thus in these tumours the surgeon removes a very wide margin of healthy brain if he hopes to extirpate the tumour. Unfortunately many of these tumours are already at the time of operation too extensive to allow of this.

The surgeon sorely needs some ancillary aid which will inform him whether or not he has got well beyond the tumour. The use of such things as fluorescein would seem to be an important help, indeed any method of showing up tumour tissue would be an outstanding advance in the surgery of gliomata.

The cerebral astrocytomata should at present be regarded as being irremovable in most patients. Operation is often necessary to relieve symptoms of raised intracranial pressure, and this incident having been successfully passed, surgery probably has little more to offer. The oligodendroglioma in some cases can only be dealt with on similar lines, but there is no doubt that when a tumour seems to the surgeon to be localized, he should endeavour to extirpate it. My experience with the cerebral ependymomas has been small, and—in spite of Scherer's statements—the results disappointing. Nevertheless extirpation should be the method of choice until we know more about them. Before leaving the surgical aspects of gliomata, I would like to raise the question of non-dominant hemispherectomy for a tumour such as an oligodendroglioma or perhaps an astrocytoma which by such a radical procedure might be completely and permanently removed. I was much impressed by the recent report by Bell and Karnosh of such a case of astrocytoma, the patient being alive and well ten years afterwards. It would appear that the consequent disability is not so severe as might be expected. I think the possibilities of such operations should be explored, at any rate tentatively, and would be justified in view of the present position of the treatment of gliomata.

Finally a word must be said about radiotherapy for gliomata. An increasing number of such tumours are being treated in this way, and, in truth, we have nothing else to offer after the surgeon has performed some palliative operation. It is difficult to obtain a parallel series of cases with and without radiation, for no two cases are alike, and the similarity or otherwise of the tumours cannot be determined until a post mortem has been made. The comparison cannot be made as with, say, a series of cases of pituitary adenoma. But we have all seen individual patients in whom, judging by clinical methods, there is no shadow of doubt that radiation has caused retrogression of the tumour to a greater or less degree. And this holds good for each of the common types of glioma. Yet the hope of ultimate cure is negligible. This is a problem to be solved by the radiotherapists, and I cannot help feeling that eventually the treatment of extensive malignant growths in general will lie in this direction, or with some similar physical method as yet undiscovered, or else along a biological approach. In the meantime it appears that radiotherapy leaves much to be desired. With the advent of high voltage apparatus, radionecrosis has become a recognized danger. There is also the possibility that at the borderline of maximum tolerance of the brain tissue, certain changes around a glioma described clearly by Carmichael and which may be a defence mechanism against invasion, may be endangered. Some of the unpredictable and surprisingly long survivals after partial removal of gliomas may be due not to radiation entirely, but to natural defences. If the brain has a natural defence against certain gliomata, it should never be damaged by irradiation. This is a problem to be studied along with that of the optimum time—dose factor for the gliomata.

Dr. Gerald Parsons-Smith: In a series of 150 verified cases of cerebral tumour I found that the electroencephalogram had some diagnostic value in cases of cerebral glioma. The E.E.G. should show a focal abnormality in the affected hemisphere in the great majority of supratentorial gliomata even before the patient develops abnormal physical signs. Although such a unilateral focus was found in 88·5% of astrocytomata and 87% of the malignant gliomata, the position of the maximum electrical abnormality was found to coincide with the actual site of the glioma in only 74% in each group. The E.E.G. should not be employed to demarcate the *anatomical limits of a glioma*, as this can usually be done more accurately by the various radiological methods, but rather it should be used to illustrate *the extent and the degree of the abnormal brain tissue around a tumour*, and also the direction of the tumour spread. It was a comparatively easy matter to distinguish the infiltrating lesions from such conditions as cerebral abscess and subdural hæmatoma, but the E.E.G. appearances produced by the various gliomata were not specific and it was not possible to differentiate between them. After operation and deep X-ray therapy the earliest evidence of recurrence of a glioma could be found in the E.E.G. which also reflected the slightest change in cerebral metabolism produced by the progress of a tumour in the posterior fossa.

Mr. G. K. Tutton: The experience from Manchester in Professor Geoffrey Jefferson's Clinic is almost exactly comparable to that recounted by Mr. Pennybacker and Mr. Northfield.

I would agree with them that the outlook in all but one or two cases is most depressing. Although there have been at least two cases of survival for twelve and fourteen years which support Mr. Northfield's contention that more radical surgery should be the rule, we now believe that a more realistic view towards the gliomata in the cerebral hemispheres should be adopted.

Operations on the glioblastoma multiforme, except those made for a biopsy, are rejected so far as possible.

We try to make a precise pathological diagnosis by arteriography, and where the typical appearance of these tumours is shown no operation is suggested.

Extensive internal decompressions for palliation and social reasons are sometimes done for these tumours in the frontal lobes.

In my opinion the most significant trend in the management of the gliomata is the present emphasis placed on the *pre-operative assessment* of the pathology of the tumour.

Unquestionably the development of percutaneous angiography, which, unlike ventriculography, does not necessitate immediate subsequent operation, is at present the most valuable means of attaining this end.

I have analysed the last 100 cases of glioma in the cerebral hemispheres seen in the Neurosurgical Service in Manchester during the past eighteen months.

There were 55 glioblastomata, 37 astrocytomata, 5 oligodendrogliomata, 1 ependymoma and 2 unclassified.

Angiography was performed in 31 of the glioblastomata and in 27 of these a typical tumour pattern was seen. In only 4 was there no pattern. In general the massive vascular marking with numerous abnormal vessels gave the diagnosis, and in many cases we were thus able to avoid craniotomy.

A diffuse blush in the arterial phase sometimes led to difficulty but we have learnt that the blush of a meningioma usually occurs in the phlebograms.

Secondary tumours, of which there were 10 in the same period, can mimic the typical appearance of a glioblastoma and in 3 of them there was a diffuse blush in the phlebograms which suggested meningioma. 22 angiograms were done in the 37 astrocytomata and all but 2 showed no tumour pattern at all. However, there was obvious distortion of one or more of the main cerebral vessels. In the two with the tumour pattern the diagnosis of astrocytoma was made on the sections although macroscopically we thought the tumours to be glioblastomata.

I think this apparent anomaly could be explained by dedifferentiation in these tumours.

The numbers of the remaining gliomata are too small for useful analysis.

We have also found the electroencephalogram of great value in localising the side of the tumour for subsequent arteriography. In our experience chronic subdural hæmatoma and cerebral abscess can nearly always be diagnosed by the electroencephalogram.

In view of the great shortage of hospital beds major operation on the gliomata are, therefore, avoided as far as possible.

After clinical examination an electroencephalogram is done to find on which side the tumour is situated if this is not already known.

If a percutaneous angiogram is equivocal as it is with mid-line tumours and some of the astrocytomata, ventriculography or encephalography is done.

The number of ventriculograms has fallen by nearly one-third.

DISCUSSION ON OBESITY

Dr. A. W. Spence: The pathogenesis of obesity is difficult to understand. It is my usual experience to have obese patients referred to me as suffering from what is termed "some endocrine disorder", or from "pituitary dysfunction", or as cases of hypothyroidism. The matter, however, is not so vague nor so simple as that, for in the bulk of cases there is no obvious evidence of any endocrine disturbance whatsoever. This does not mean that an endocrine disturbance is not the cause, but the suggestion that it *is* the cause is hypothetical. I propose to discuss mainly the pathogenesis and treatment of the condition.

PATHOGENESIS

The endocrine system. The Gonads.—The gonads have priority because from the earliest times castration has been practised in order to fatten livestock. From this experience it would seem that the fattening process in these animals is dependent on a deficiency of testicular secretion. The typical picture conjured up of a eunuch is that of a very obese person, but though it is true that eunuchism and eunuchoidism may result in obesity, this is not always so; eunuchs are said to be approximately one-half tall and slender and one-half short and fat. A cross section analysis of normal men is not greatly different (Moore, 1935).

Only one testicular hormone has so far been isolated, namely testosterone, and in my experience and in the experience of others testosterone has little effect on the obesity in these conditions.

It is well known that obesity may occur in women at the time of the menopause, but neither œstrogen nor progesterone is effective in reducing the excess of fat, and obesity is not a feature of ovarian infantilism in which there is a failure of ovarian development. Experimentally there is no definite evidence that the administration of the male or female sex hormones exerts any influence on fat metabolism, although perhaps testosterone may increase the storage of fat.

Thyroid.—A common fallacy is that obesity is often due to hypothyroidism. Many of the patients thus labelled have none of the features of hypothyroidism and a determination of the basal metabolic rate is inaccurate owing to the large surface area of the body. Although obesity may occur in myxœdema and hypothyroidism, it is not the rule, the thyroid being more concerned with protein than with fat metabolism.

The adrenals.—It is probable that the adrenal cortex produces compounds which affect the metabolism of fat and cause obesity. Gross obesity may occur in patients with an adrenal cortical tumour. It is usually not characteristic of the androgen-producing tumours which give rise to the adrenogenital syndrome, but it is a feature of those adrenal tumours which are responsible for Cushing's syndrome. These tumours produce corticosterone and corticosterone-like hormones. Kendall (1945) has shown that the administration of corticosterone or of 11-dehydrocorticosterone to certain strains of mice increases the amount of fat in the animal. However, the experimental evidence of the existence of an adrenal hormone which promotes the deposition of fat is meagre. Albright (1943) has suggested that the obesity associated with adrenal tumours is due to excessive conversion of protein into glucose by corticosterone and the subsequent conversion of glucose into fat.

Pancreas.—Obesity may be caused by hyperinsulinism, due to a tumour or to hyperplasia of the islets of Langerhans. Although a low glucose tolerance curve is present in a high proportion of adipose persons, and Lawrence (1941) has shown that an important action of insulin is the conversion of carbohydrates into fat, there is no clear evidence that their obesity is due to excessive secretion of insulin.

Middle-aged diabetics are often fat. I tentatively suggest that sometimes obesity combined with hyperglycæmia may possibly be the result of adrenal hyperfunction and may be in the nature of an incomplete Cushing's syndrome.

The pituitary.—The pituitary gland is usually implicated as being the cause of obesity, a popular diagnosis being "pituitary dysfunction", which could mean either hyperpituitarism or hypopituitarism. The common belief that hypopituitarism is a frequent cause of obesity dates from Fröhlich's original description of obesity occurring in children with a pituitary tumour and from the early experiments on partial ablation of the pituitary, whereby the animals so treated became obese. I cannot subscribe to this view. Although it is true that obesity may be associated with a pituitary tumour, it is equally true that it may not be.

The thyrotrophic hormone is the only pituitary hormone a deficiency of which may possibly cause obesity. The combination of pituitary infantilism and obesity, however, is rare. The low basal metabolic rate observed in Simmonds's disease and other forms of hypopituitarism is presumably due to deficiency of thyrotrophic hormone and yet these patients are not obese—in fact, the opposite is often the case.

With regard to hyperpituitarism, obesity may occur in acromegaly and in Cushing's syndrome. For this reason it has been suggested that the adiposity is due to hyperpituitarism. Against this opinion is the observation that acromegalics as a whole do not tend to be fat. In my view the obesity of Cushing's syndrome is due to hyperfunction of the adrenal cortex, secondary to hyperpituitarism. Some observers have affirmed, however, that the obesity of Cushing's syndrome is only apparent, the bulging abdomen being due to osteoporosis (Albright, Parson and Bloomberg, 1941).

Simpson (1948) has ascribed puberty obesity and climacteric obesity to hyperactivity of the anterior pituitary. This is possible, but it is more likely to be through its action on the adrenal cortex rather than through a primary effect.

Pregnancy.—It is not uncommon for obesity to occur rapidly after pregnancy. The cause of this is obscure, but during pregnancy there is undoubtedly hyperfunction of the anterior pituitary and of the adrenal cortex.

Over-eating.—Obesity has been classified as endogenous, when it arises through some disturbance within the body, and exogenous, meaning that over-eating is the cause—a classification which is falling into disrepute. The suggestion has been made that some of these patients have a pathological hunger akin to the pathological thirst of diabetes insipidus and it has been postulated that this is due to excessive secretion of insulin, as I have already indicated. I do not consider, however, that over-eating is responsible for many cases of obesity; in my experience the majority of patients affirm that they eat little. If over-eating is a factor, the problem of obesity is somewhat simplified, but not entirely solved, since some thin people have hearty appetites and yet remain thin.

The hypothalamus.—The hypothalamus may play a greater part in the genesis of obesity than is generally supposed. Smith (1926) showed that obesity was produced in his laboratory animals not by removal of the anterior pituitary, but by injury to the tuber cinereum. It is

probable that in the earlier experiments in which obesity occurred after removal of the pituitary the hypothalamus or tuber cinereum was also damaged. Hetherington and Ranson (1942) showed that the presence of the pituitary is not essential to the appearance of hypothalamic obesity. Clinically, it is well known that obesity may arise as a sequel to diseases such as encephalitis and meningitis which damage the hypothalamus.

Those pituitary tumours which cause obesity probably do so, not by interfering with pituitary function, but by pressing on the hypothalamus. The obesity of Fröhlich's syndrome is due not to a pituitary but to a hypothalamic lesion. It has been shown that there are centres in the hypothalamus which regulate menstruation via the anterior pituitary and that disturbance of these centres by impulses from the higher centres, produced by emotional causes, results in amenorrhœa (Theobald, 1936). This condition is not infrequently accompanied by obesity, suggesting that other centres in the hypothalamus are also affected. Although it has been established that there are nervous and vascular connexions between the hypothalamus and the pituitary, I doubt whether hypothalamic obesity arises as a result of a secondary disturbance of anterior lobe function, as in the case of amenorrhœa, (1) because of the animal experiments already mentioned, and (2) because clinically there may be no evidence of anterior pituitary disturbance.

On the other hand, it may be argued that it is rash to consider a disordered hypothalamus as a cause of obesity when other evidence of hypothalamic disturbance is absent. I do feel, however, that the hypothalamus may be the centre of a weight-regulating mechanism, whatever that mechanism may be, which controls the breakdown and storage of fat. A different "gearing" of this mechanism may explain certain cases of sporadic, familial and racial obesity.

Water retention.—Water retention may be present in obese patients and this may even be shown by pitting œdema. Associated with the retention of water there may be diminished excretion of sodium chloride. Harris (1947, 1948) has demonstrated that stimulation of the neural stalk of the pituitary in rabbits produces inhibition of water diuresis. Verney (1946), who found that water diuresis in the dog can be inhibited by subjecting the animal to muscular exercise or emotional stress, has suggested that this is due to secretion of an antidiuretic hormone by the posterior pituitary. There is also evidence that the anterior lobe promotes diuresis (Shapiro, 1938), an intact anterior lobe being necessary for the polyuria of diabetes insipidus. Hence the water retention which may accompany obesity may be due to disordered function of the hypothalamus, resulting either in increased secretion of the posterior lobe antidiuretic hormone or in decreased secretion of the anterior lobe diuretic hormone.

From this review it will have been seen that we know very little concerning the causation of obesity.

Obesity in children.—In my experience any child who is fat is labelled as having Fröhlich's syndrome, especially if there is present what appears to be genital hypoplasia. Fröhlich's syndrome is rare and is caused by an organic lesion affecting the hypothalamic-pituitary connexions. The commoner syndrome resembles Fröhlich's syndrome in its clinical features, but it differs from Fröhlich's syndrome in that it is not caused by a gross pathological lesion; sexual development is merely delayed, and after puberty a good deal of the fat is lost spontaneously.

Treatment

Endocrine obesity.—Endocrine obesity is obesity due to an obvious endocrine disorder. Loss of weight may follow removal of or radiotherapy to a pituitary tumour and the obesity of Cushing's syndrome may respond to removal of the adrenal tumour—if this be the cause—or to irradiation of the pituitary. In hypogonadism, although testosterone does not cause loss of weight, some of the flabby fat may be lost as a result of its use. If hypothyroidism is the cause the administration of thyroid results in loss of weight, but otherwise its use is disappointing. The increase of weight at the menopause is unaffected by the administration of œstrogen. In all cases of obesity the administration of pituitary extracts is valueless.

Reducing diet.—The fundamental treatment of most cases of obesity, i.e. those which have no obvious endocrine disturbance, is a reducing diet. Such diets consist of a very low fat and carbohydrate content and, because of its specific dynamic action, a high protein

content, the total calorie value per day being about 1,000 calories. The diet, being deficient in vitamins A and D, should be supplemented with a vitamin concentrate. As there may be a retention of sodium chloride and water, fluids should be limited to 2 pints a day and the intake of salt reduced to a minimum.

It is a remarkable fact that sometimes weight is lost more rapidly when the patient is treated at rest in bed than when up and about.

Patients should lose about 2 lb. a week. When the desired weight has been reached, the diet should be increased, but not so much as to cause a further gain in weight. Most patients will always have to be careful of their food intake.

Dextro-amphetamine.—5 mg. of dextro-amphetamine may be given before breakfast, at 11.0 a.m. and at 4.0 p.m. to reduce appetite, should patients find adhering to the diet difficult. At the same time it induces a sense of well-being and as far as I am aware in these doses it has no harmful side-effects.

Thyroid is rarely necessary, but it may be given in conjunction with the diet if results with the diet are unsatisfactory. In my experience obese patients are often resistant to the action of thyroid. In these cases there is no point in giving more than 3 grains a day.

Diuretics.—In view of the water retention which may be present, diuretics are theoretically indicated, but I cannot say that I have been much impressed with their effects in obesity. A mercurial diuretic is given intramuscularly in doses of 2 c.c. two or three times a week.

Physiotherapy.—Exercise will help a little, but not so much as is generally thought. For most obese patients it is exhausting. Massage, purgation and Turkish baths are of very limited value.

In children.—Whether a reducing diet should be given depends on the degree of obesity. In general it should be avoided, for it is a hardship; further it is doubtful whether the child will keep to it and in boarding schools it is impossible. Thyroid is unnecessary if there is no evidence of hypothyroidism. Usually little improvement is obtained unless it is given in toxic doses which is undesirable. It is well known that many children who are overweight lose their excessive weight spontaneously after puberty.

Professor E. C. Dodds: Excluding the classical syndrome with an endocrine background associated with obesity, there is very little to say about its cause or treatment that has not already been said many times over. The treatment consists either of disguised starvation; or of some form of increasing the energy output such as the stimulation of the metabolism by hormones, for example, thyroid, specific dynamic action by proteins, polynitrophenols such as dinitro-ortho-cresol, and exercise.

All of these methods have been reviewed at very great length and we know that thyroid extract is no answer to the problem because one has to produce far too great a rise in metabolism to effect sufficient consumption of fat to cause loss of weight. Specific dynamic action is unfortunately out of the question owing to the difficulty of getting meat, whilst the polynitrophenols are too dangerous because of the fear of death from hyperthermia and of a development of cataract.

Again exercise is a very severe method of counteracting obesity as one has to perform such a lot of exercise in order to reduce weight. Some years ago I made some calculations which I published in an Address at the Middlesex Hospital, and these melancholy findings have been quoted as a warning to fat people on several occasions. For example, it can be calculated that the maximum output of energy for short periods is at the rate of 600 calories per hour. Very few people can maintain this rate and the average person will find great difficulty in putting out more than 300 calories in a half-hour game of squash rackets. This is equivalent to two slices of bread and butter, or alternatively, two dry Martinis. Every pint of beer requires half an hour of squash, or, if the person is not capable of expending energy at this rate, the equivalent of a five-mile walk would just about equal it. A glass of champagne corresponds to about ten minutes' squash whilst a double whisky and soda would require the full half-hour.

An even more depressing calculation is that during an average dinner in pre-war days something between 700–800 calories could be consumed in the form of alcohol. In order to work this off it would be necessary to play squash for five and a half hours, or alternatively, to climb Ben Nevis several times.

The real problem with which we are concerned is that we do not really understand the mechanism of weight regulation. General experience shows very clearly that subjects fall under two headings: (*a*) people who maintain a constant weight over many years despite excessive intake of food, and (*b*) the second group who respond immediately to an increase in calorie intake by the putting on of weight. Between these two groups there are subjects who vary in their power to put on weight according to intake. The two main groups have been noted by many clinicians and many explanations have been put forward to account for the persons who remain at a constant weight despite their calorie intake. The two most important suggestions are, firstly that their digestion or absorption is poor with the result that a considerable proportion of the food passes out undigested and unabsorbed in the fæces. The second theory to account for the maintenance of weight at a constant level is that the metabolism of these subjects is stimulated by the food they eat and that they have an exaggerated specific dynamic action.

Dr. Mary Ransome and I have performed a number of experiments of which the following is a brief summary:

The first investigation consisted of taking people who had a record of constant weight over many years and assessing their normal dietary intake. The subjects were then given an intake of double and treble their normal, and in some cases they were kept in bed. We had little difficulty in confirming that there did exist this group who, under the most carefully controlled conditions, failed to put on weight even when given excessive quantities of food. A careful analysis of the fæces failed to indicate any increase in the output of nitrogen or fat. Microscopic examination showed very clearly that the digestion was normal. This confirmed what has already been published by a number of other workers, namely that the explanation on the lines of comparison of digestion and absorption cannot be advanced in this case. Whilst it is too early to give a very definite statement, our respiratory metabolism investigations indicated quite clearly that these subjects responded to a high diet by an increase in their basal metabolic rate, whereas the corresponding controls who put on weight readily, showed no such increase. This line is being actively pursued, and may provide additional evidence for the view that the explanation for the phenomena of the person with the constant weight is that they have a much more resilient metabolism capable of being stimulated to deal with a sudden increase of food.

I prefaced my remarks by stating that we knew very little about the mechanism of weight control and I think very few people realize that an astonishing mechanism must be in constant operation. If one weighs the subject at the same time of the day, say on rising in the morning, the weight of the individual is astonishingly constant, assuming that the subject is neither gaining nor losing weight, the weight remains constant to within roughly 1 lb. and this means, in the person of average weight, a reproducibility of between 0·5% and 1% on a weight of over one hundredweight. This is astonishing when one considers to what influences the body might be subjected in twenty-four hours, such as varying degrees of exposure, output of fluid, perspiration and so forth.

One only has to think of the elaborate mechanism which is required to maintain definite weights in a submarine or an airship to realize that there must be some underlying mechanism of very great delicacy in all animals.

This mechanism must obviously be related to something external. For example, we know that the onset of the mating and nesting of birds in the spring is associated with the intensity of light falling on their heads and necks, we know that the maintenance of temperature is due to the sensitivity of the skin through its nervous supply responding to the external temperature, thus causing sweating, &c., and I feel that there must, therefore, be some external factor to which the body reacts to keep weight constant. If one thinks about the situation it must almost certainly be that the body reacts to gravity and it is possible that there is some relation between the body and the gravitational pull. I have thought a good deal as to how one could investigate this and have conducted a series of preliminary experiments which, on occasion, have caused my colleagues to doubt my mental stability.

The ideal experiments would be to lessen the gravitational pull and, if the theory is correct, the body should increase in weight. Experiments with coal-gas-filled balloons strapped to arms of subjects could not be maintained for a sufficiently long period to evoke any response other than mirth and sardonic comments. A further attempt was made with rats supplied with chain mail binders and exposed to magnetic pull from above. This again proved to be quite impracticable. Again the weighting of subjects with sandbags introduced so many complications about the increase in work to uphold the sandbags that the experimental results defied analysis.

It appears that there is only one way to investigate this problem and that is to have an experimental centrifuge containing animals such as rats and mice and to accustom them to living their lives to revolutions. It would then be possible to adjust the speed of the centrifuge to control the gravitational pull. The design of such an instrument would, of course, be very complicated and up to the present no one has done anything in this field.

Dr. Raymond Greene [*Abstract*]: Much of the speculation and experiment about the origin of "obesity" is misdirected owing to its emphasis on fat instead of water. If we believe that people are overweight because of an excessive deposit of fat, we are confronted by a series of insoluble dilemmas in the face of which we must either deny the law of the conservation of mass, or change our beliefs. I prefer the latter alternative. Fat can only come from food, even the most vegetative patients being unable to manufacture it from the atmosphere. If an excess of that food is to be laid down as fat we are forced to postulate that the intake is excessive, the absorption abnormally efficient or the use abnormally deficient. Each proposition has been disproved by many reliable investigations. Fat people do not eat more than their fellows, and their absorption, their metabolism and their specific dynamic action are normal. We are forced by cold logic to believe that the excessive weight of these patients is not fat at all. If then we ask what it is, the answer is ready to hand. Clinical and experimental evidence shows that "adiposity" may be caused by damage to the hypothalamus, in which lies the nucleus supra-opticus, the central control station of water metabolism. Damage to this region by concussion or encephalitis or its derangement by such severe emotions as anxiety and depression often cause a rapid increase in weight. I pointed out in 1946 the similarity between the increase in weight so common in anxious women and the now classical experiments of Verney on dogs subjected to equivalent emotions. More direct evidence comes from the fact that pitting œdema is almost always demonstrable in the very "fat", usually along the shins; from the excellent results of a dehydrating regime even when this supplies ample calories; and by a single (and therefore unreliable) experiment of my own which I have never found time to extend: I assayed the true fat content of two cylinders of equal cross section of adipose tissue from the abdomens of two women, one "fat" and one thin. Though the one cylinder was four times as high as the other, the fat content was almost equal.

I conclude that the "fat" person is one whose adipose tissue is overhydrated rather than overfatted. The distribution of his "fat" depends upon the distribution of his adipose tissue. People do not keep their "sponges" in the same place, though most people seem to have one in the abdominal wall. "Fat" people differ from those whose water retention is due to cardiac or renal causes in that their excess of fluid is concentrated in their adipose tissue. Why this should be we cannot yet say, though we may guess that fluid storage is one of the physiological functions of adipose tissue.

Finally, I would like to support Dr. Spence in his condemnation of thyroid and anterior pituitary extracts in the treatment of obesity. The former in small doses may be useful as a diuretic, but urea is a better one. Apart from this slight activity it is useless in safe doses except in those rare instances in which hypothyroidism is present. The use of the latter is absurd. In the unlikely event of the anterior pituitary being to blame at all in "obesity", the fault is in the direction of overactivity. Moreover pituitary tablets are completely destroyed by the normal processes of digestion.

The President said he was one of those who have been described as possessing a weight-regulating mechanism, whatever that meant. For the past forty years he had, with the most minor fluctuations, remained at a constant weight without any restrictions in the nature and quantity of food. It had been suggested that an explanation was afforded by his addiction to regular fairly strenuous exercise but as Professor Dodds pointed out no such relationship appears to be pertinent. On the basis of oxygen consumption, the calorie value of all forms of exercise is readily computed, a litre of oxygen being the equivalent of 5 calories. And taking 1 lb. of fat as a standard of calculation, the exercise necessary for its combustion is that comprised in walking nearly 70 miles at the reasonable sustained speed of 3½ miles an hour. Needless to say the increased ingestion of food consequent on the appetite produced would more than counterbalance the loss of fat. If really violent exercise were in question, one would have to run at the rate of 10 miles an hour for 43·2 miles, to row from Putney to Mortlake nine times; or, were such a feat humanly possible, to run at full speed for 7¼ miles—say 21½ minutes for the same loss of fat.

Incidentally, one possible fallacy might be mentioned, loss of weight must be distinguished from loss of fat. He had lost 3 lb. in weight in half an hour's vigorous climbing in Switzerland and he had observed a loss of 9 lb. in a runner over a Marathon race of 26¼ miles in about two and a half hours. This was, of course, mainly water which was restored during the ensuing forty-eight hours.

He was, however, tempted to believe that there was some relation between regular exercise and metabolism although investigations *ad hoc* did not appear to support the idea of a constant higher level.

Dr. John S. Richardson: The psychological aspects of obesity are well recognized and quite extensive literature has accumulated on this subject. I shall therefore confine myself to describing a small group of cases that have recently been under investigation by Dr. H. J. Shorvon and myself at St. Thomas's Hospital. In two or three cases of marked obesity which failed to respond to dietary restriction, we found that their history contained a notable traumatic incident. The bombing of a home, the loss of a child, the desertion or suicide of a husband are examples, and were followed immediately by a rapid increase in weight. It was thought that this sudden trauma might well have led to impulses from the cortex acting on the hypothalamus in a manner calculated to alter water excretion and appetite or weight control. I wish to stress that these cases did not show any psychological disorder obvious to me, nevertheless Dr. Shorvon agreed to give them abreactions so as to see if anything would come out of it. Something did, as the abreactions produced a response that was startling in the intensity of the emotion that was released. We have now got some 20 of these cases under observation and I wish to record very briefly the results of the investigation of 12 and the treatment of 9 of these.

They were all married women between the ages of 21 and 42, the majority being round about 30. They showed considerable obesity of simple distribution in all cases save one, that was typical of the so-called "pituitary" obesity. Their family history was interesting in that it showed that in one-quarter the parents were unsatisfactory or frankly bad, in another quarter one or other parent was unsatisfactory, while in half both parents were either good or mediocre, but the father was almost always strict and the mother over-indulgent. The patients' previous personality study and medical history showed that only one, who was a psychopath, had had periods of instability, and their intelligence was average or above average in all cases except this one. Three-quarters were childless and two-thirds had had no knowledge of sexual matters before marriage and most had not made satisfactory sexual adjustment. None of them had been fat before the traumatic incident which was single in 9 and multiple in 3 cases. All showed a rapid and considerable increase in weight after it, associated with irregular periods in 5 cases and amenorrhœa in 2.

Dr. Shorvon found hysterical symptoms in 3 cases, obsessional tendencies in 3 and anxiety traits in 2, and the psychopath to whom I have already referred. They are therefore a group of formerly slim, young married women of average intelligence without previous neurotic illness who were mostly unhappy at home and rigidly brought up in sexual ignorance.

All 9 cases who had abreactions lost weight that, expressed as a percentage of their weight before treatment, averaged out at 13%. The average length of time it took to lose this weight was six months, the average number of abreactions done during this time was twelve. In none of these 9 cases was there a failure to lose over a stone in weight although no other weight-reducing method was employed, but one case that did not have abreactions made no response whatsoever to rigid dieting and dehydration methods. This loss of 13% of the body weight before treatment may be compared with a loss of 23% in married women of the same age treated for the same time as out-patients with dietetic restriction and benzedrine.

I wish to make it quite clear that we do not consider abreactive techniques as a treatment for obesity. What we do say is that these techniques have shown that traumatic incidents followed by obesity in some women are associated with an extremely high emotional content that may well be unsuspected by the general physician or practitioner as the patients do not appear neurotic in the commonly used sense of the word. The release of the emotions by abreactions has been followed in all 9 of our cases by a considerable loss of weight in spite of the fact that no dietary or other measures were adopted. We hope therefore that abreactions may be helpful in managing certain selected cases of obesity by giving relief to a previously unsuspected disorder with subsequent loss of weight.

Dr. W. S. C. Copeman thought that the two points which had been made by the preceding speakers—namely adiposity and abnormality in the distribution of body fluid—could be considered merely as differing aspects of the physiology of fat.

The actual deposition of fat in abnormal quantity was of course of basal importance. He also believed, however, that in man, as in the camel, fat constituted a normal water-storing organ, and that rapid changes both in quantity and in tension could occur under certain circumstances. These changes could give rise to clinical signs and symptoms in the patient.

DISCUSSION: HÆMOLYTIC DISEASE OF THE NEW-BORN

Dr. R. R. A. Coombs (*Department of Pathology, University of Cambridge*): My remarks on the theoretical basis and comparative side of this disease may be considered under four headings:

(1) *Some factors in the pathogenesis of the human disease which are imperfectly understood.*—By 1946 our knowledge of this disease, from the clinical side, could have been viewed with some satisfaction: the diagnosis could be confirmed unequivocally by serological tests and the perfection of the techniques of transfusion and exchange-transfusion appeared to be reducing the mortality rate substantially. Simultaneously workers in blood-grouping laboratories were continuing their most fruitful work in disentangling and characterizing further subgroups of the blood-cell antigens which may be responsible for the disease.

From the biological point of view, however, we were no closer to understanding in what way the natural safeguards against iso-immunization in pregnancy operated. It is difficult to believe that there is any teleological purpose in eliminating at birth certain heterozygous children. If such a purpose exists, it would merit investigation but I think the converse of this line of thought will probably prove more helpful; namely, how does Nature in nearly all cases of pregnancy guard against the consequences of an immunization of the mother by antigenic body constituents of the embryo determined by genes derived from the father? In considering fœtal antigens we must include not only red-cell constituents but all body constituents and extra-embryonic fœtal tissues as well.

If one considers from the theoretical point of view various aspects of hæmolytic disease of the new-born the following appear to be some of the problems still waiting to be satisfactorily answered.

(i) What is Nature's exact protective mechanism against iso-immunization of pregnancy in matings heterospecific as regards especially the A, B and O antigens and also other antigens and in what way does the Rh system of antigens and their related biological phenomena differ from this?

(ii) What is the protective mechanism at work in the many normal pregnancies resulting from a mating of an Rh positive to an Rh negative person where the infant is also Rh positive?

(iii) What are the factors determining the many varied clinical manifestations which may result from iso-immunization with the D antigen?

(iv) What determines the much greater antigenicity of certain of the Rh antigens for the human subject?

Bearing these problems in mind we may now consider what may happen at various stages both during and after pregnancy, by taking the case of any hypothetical blood or tissue group antigen inherited by the fœtus from the father and which is foreign to the mother.

The first matter to consider is how early or late in fœtal development this substance manifests itself in an antigenic form in the embryo tissues themselves or in the fœtal placental tissues which may be more important.

Secondly, how antigenic is this substance? The A and B and certain of the Rh substances are very antigenic but some, such as M and N and other Rh substances, are apparently less so.

Thirdly, do fœtal antigens reach the maternal tissues in every pregnancy and, if so, are they necessarily still in an antigenic form? It may be that during fœtal metabolism these substances in the embryo or fœtal placental tissue become degraded and reach the maternal tissues in a non-antigenic form—but here, depending on the constitution of the mother as one may postulate in certain allergic conditions, the substances may couple with maternal protein and so become converted into potential antigens again.

At this stage one might encounter the first natural safeguard against the possibility of iso-immunization of pregnancy. For instance, the heterologous fœtal antigens may be fixed in the maternal placenta by free or even sessile specific receptors and while anchored they may be degraded locally before being able to reach the antibody-producing tissues of the mother. However one must bear in mind the possibility of the production of antibodies by the local placental tissues of the mother.

The fœtal antigens if not fixed by the maternal placenta may enter the maternal circulation and produce an immunization if the host is susceptible to such an immunization—I stress "if the host is susceptible" for at the moment we divide persons into Rh positive and Rh negative, by whether they contain the Rh antigen on their red cells or not. However, it does seem at least hypothetically possible that some persons so classified as Rh negative although containing no Rh positive substance on their red cells may yet contain this substance as a constituent of some other tissue cells and so would not be susceptible to immunization with the Rh positive substance. I do not think this is the case, however, especially in the light of reports that about 46% of Rh negative persons receiving random or Rh positive blood in the form of transfusions have been shown to produce Rh antibodies (Pickles, 1949). Nevertheless it is a concept which should be kept in mind.

Supposing the process has reached the stage where the mother has produced antibodies against fœtal antigens, there remain further ways in which the fœtus could be protected.

In the first place the placenta in many animal species is fairly impermeable to the passage of antibodies into the fœtus. This may not be such a good protection as it may seem at first and this matter is reconsidered later. Meanwhile we may consider what may happen in the case where the placenta is permeable to the passage of antibodies. In the fœtal placenta there is again the possibility of the maternal antibody being neutralized by free or attached specific fœtal antigen and thus protecting the fœtus itself from the action of the antibody. This is considered to be very likely in the case of the A, B, and O antigens, and may also take place with certain of the Rh antigens; however, this seems unlikely in the latter case for, were it so, one would expect to find many Rh positive infants showing no evidence of the presence of maternal antibody although their mothers showed a definite post-partum rise in antibody titre. Van Bolhuis (1948) found that 16 out of 121 placentæ from Rh positive infants were capable of neutralizing the D Rh antibody, but rather than allowing this to be a protective mechanism the author lays on this fact the responsibility of the immunization of the mother. He came to this conclusion because when he examined the placentæ of Rh positive affected infants 27 out of 31 showed this inhibitory action on the Rh antibody. A confirmation of this work would be most valuable.

We may now reconsider the animals whose placenta is impermeable to antibodies. In these cases the maternal antibodies become concentrated in the first colostrum, the protein of which may be absorbed in its native state by the new-born animal through the alimentary canal. By this route there would seem to be no further possible specific barrier to neutralize the maternal antibodies before they reach the tissues of the new-born animal. So the two modes of protection might have to be weighed up: (*a*) Passage of antibodies *in utero* with the possibility of a specific neutralization in the fœtal placenta, or (*b*) protection from the antibodies till the neo-natal stage with no opportunity of a specific neutralization.

Finally we must consider what may be the significance of the maternal antibodies gaining access to the fœtus or new-born animal and sensitizing some of its cells, whether blood cells or tissue cells. Is this sensitization *per se* lethal to the actual cells themselves or the animal as a whole? One calls to mind cases of acquired hæmolytic anæmia after splenectomy. Dr. Heard's observations on rabbits are also pertinent to this question.

Such are the problems which arise in considering a hypothetical case of an antigenically incompatible pregnancy but another very important matter which must be mentioned is kernicterus. A vital question here is whether the neural lesions are due directly or are in any way related to the specific action of the Rh or other antibody, or are they non-specific in the immunological sense and due to a high concentration of hæmolytic or other degradation products. The distribution of the lesions could well be due to local concentrations of the Rh substance in these tissues. Dereymaeker (1949) believes that the lesions are due to a specific immunological action and he records experiments showing that the tissues of these nerve centres are capable of absorbing Rh antibodies. The fact that the blood-brain barrier in the adult is practically impermeable to antibodies does not vitiate this hypothesis for the blood-brain barrier of the late fœtal or early neo-natal infant might have quite different physiological properties.

(2) *The experimental production of the syndrome in laboratory animals.*—In 1946 we considered that it would be much easier to investigate these varied problems if we could produce the syndrome of hæmolytic disease experimentally in a laboratory animal; we chose the rabbit because we believed it to have a placental structure fairly similar to that of the human. The results of this investigation are described by Dr. Heard but it may be said, that so far as our experiments have gone, the rabbit may not fulfil the requirements we desire for this work.

We then attempted to produce the syndrome experimentally in the guinea-pig and the results of this investigation are described by Dr. Mynors. Work on these two animals, however, is still in progress and further experiments may throw some light on the biology or pathology of this disease.

(3) *Studies on the comparative side of the disease in certain domestic animals.*—In 1948 the opportunity arose to study the disease in thoroughbred horses and in mules, a study which was interesting from both the standpoints of comparative pathology and veterinary medicine.

Caroli and Bessis (1947) were the first to draw attention to the condition of icterus gravis in new-born mules and to show that it was due to an iso-immunization of pregnancy. Previously this condition, which is said to cause an 8% mortality of new-born mules born in the Poitou district of France, had been attributed to piroplasmosis. In the 1948 foaling season Caroli and Bessis invited me to France and together we investigated the serological procedures for diagnosis by techniques analogous to those used in the diagnosis of the human disease. Bessis was also experimenting with exchange-transfusion as a therapeutic measure in mules.

In the same year at Cambridge and Newmarket a large team of workers investigated the condition in new-born thoroughbred foals (Coombs, Crowhurst, Day, Heard, Hinde, Hoogstraten and Parry, 1948). Out of 9 cases of neonatal jaundice we confirmed by serological tests that six were due to iso-immunization of pregnancy. These cases were investigated from their clinical, serological, pathological and hæmatological aspects.

In America, Bruner, Hull, Edwards and Doll in numerous papers have described their experiences since 1947 with this condition in foals and have made many interesting observations. (Bruner, Hull and Doll, 1948; Bruner, Hull, Edwards and Doll, 1948). These workers have also described experiments on this syndrome in new-born piglets (Bruner, Brown, Hull and Kinkaid, 1949)—a study which I feel will repay further investigation and may throw light on piglet anæmia.

Experimental work on producing this syndrome in dogs has been carried out both by Eyquem (1948) who was studying particularly the cerebral lesions and their relation to kernicterus, and by Young, Erwin, Christian and Davis (1949). The latter also refer to a report by Abelson on what appeared to be naturally occurring cases of hæmolytic disease in new-born dachshunds.

The study of this disease in animals is all the more difficult on account of the fact that we know so very little about their blood groups. We are now producing at Cambridge anti-globulin sera for the diagnosis of the condition should it arise in bovines, pigs, dogs and cats;

and we already possess diagnostic sera for humans, horses, rabbits and guinea-pigs. We would be very pleased to examine the blood of suspected cases in any of these species. A small sample of clotted blood from the new-born animal is all that is required for the laboratory tests.

(4) *Some experimental laboratory investigations on problems having a direct bearing on the disease.*—Returning to the human disease, it can be appreciated how important it is to know the exact distribution of the Rh substance in the body; whether it is found in secretions or tissues other than the red cells. Boorman and Dodd (1943) found that the Rh antibody was absorbed by most of the organ tissues of Rh positive persons. The organ suspensions were prepared by grinding post-mortem material and washing it free of the blood constituents. They found no absorption by similar material derived from two Rh negative persons. It would appear from these results that the material from the two Rh negative persons did not contain the antigen in the tissues. In the case of the experiments with tissues from Rh positive persons, although Boorman and Dodd's conclusions that these tissues contain the antigen seem highly probable, there is the possibility of small amounts of red cell stromata still being present in these tissue suspensions and being responsible for this absorption. However these authors had considered this and were confident that the absorptions were due solely to the presence of the Rh substance in or on the actual tissue cells.

Dereymaeker, as already mentioned, demonstrated absorption of the Rh antibody by certain tissues of the brain. Van Bolhuis also showed the presence of the substance in a proportion of placental tissues and Witebsky and Mohn (1945) demonstrated an apparently soluble form of the substance in a percentage of amniotic fluids.

It may be that studies on this aspect of the problem will shed light on the syndrome and at Cambridge, in collaboration with Dr. Boursnell, we are starting work on this question by attempting to demonstrate the presence of the Rh substance in the various tissues with the aid of Rh antibodies tagged with a radio-isotope. Ganglion cells in the brain and the placental tissues will be among the first tissues to be studied.

A very important study is that of the isolation, identity, standardization and therapeutic application of the so-called Rh hapten (Carter, 1949).

Dr. Lythgoe of the Department of Organic Chemistry at Cambridge has, on two separate occasions, prepared extracts from about 400 c.c. packed washed Rh positive cells strictly according to Carter's published specifications. In both cases we have not been able to show any specific activity against the D Rh antibody whether using the specific inhibition test or the complement fixation reaction. We have also tested a sample of the hapten sent to us by Dr. Carter which she said was active at a dilution of 1 : 3,000. Again we could not show any inhibition of the D antibody. We find this most puzzling and can offer no explanation at present, unless it is connected with some very delicate physical state of the substance.

There are a host of problems connected with hæmolytic disease in man and animals which are awaiting elucidation. Many of these problems could be studied best by reproducing the disease experimentally in a laboratory animal for in this way the process could be followed by experimentation through the various stages of its development.

Dr. C. A. Holman: I have been asked to confine my observations to the human aspects of hæmolytic disease. Table I shows an analysis of the last two years' work at Lewisham Hospital during which time my laboratory has recognized 164 cases of Rhesus iso-immunization in women attending the local ante-natal clinics. The results of these pregnancies were as follows:

TABLE I.

20 born dead	Miscarriage	2
	Macerated stillbirth	6
	Hydrops fœtalis	11
	Stillbirth (prolapsed cord)	1
104 born alive—Cell Coombs–Positive (i.e. affected)	Death from icterus gravis	8
	" " kernicterus	6
	" " cerebral hæmorrhage	3
	" " prematurity	1
	Survived—developed kernicterus	4
	" normal to date	82
14 born alive Rhesus positive Cell Coombs–negative	All normal and survived	14
26 Rhesus negative	Survived—normal	24
	Died—of prematurity	2
		164

The Rhesus antigen D has been shown to be the commonest cause of human hæmolytic disease. Other Rhesus antigens C, E, c and C^w have been occasionally involved as has the Kell antigen. In the present series the D antigen or D and C together were responsible in 162 cases and E and c in one case each.

It is not possible to provide an accurate picture of the incidence of the various types of the disease as, although we are now able to diagnose almost all the cases, the measures taken to combat the disease may alter the severity of the cases and will certainly modify the clinical manifestations. The present series was likely to be modified by the practice of inducing labour at 36 weeks, or as soon afterwards as the infant appeared to have achieved a satisfactory weight. In the first half of the period reviewed, almost all of the affected children received replacement transfusion whereas in the second half only those with cord hæmoglobin levels of under 14 grammes % were given this treatment.

Surveying the detail of the chart one sees the low incidence of miscarriage which I think implies that hæmolytic disease is not usually responsible for death of the fœtus in the first three to four months of fœtal life. The relative proportions of macerated stillbirths and hydrops fœtalis were the reverse of those seen prior to induction of labour, suggesting that the earlier delivery prevented maceration occurring in so many cases and that the macerated stillbirth is simply a later stage in the same process. The proportion of stillbirths has been reduced although that of very severe icterus gravis is greater, which means that there is not a great change in the total mortality. If, however, an infant is born alive there is at least a chance of saving it. It appears to me from the pattern of the disease that hydrops fœtalis is the result of the same process which produces icterus gravis and is just a more severe manifestation.

It is now possible to recognize the mildest degrees of the affection by the use of the Coombs' test and it is clear that a weakly positive Coombs' test is compatible with a normal child who shows neither jaundice nor anæmia. I feel that the induction of labour at 36 weeks helps some children to escape altogether, i.e. the group which are Rh positive and Coombs' negative. This is not unreasonable in that it is known that placental permeability increases at this time. Even if, as had been suggested, the Coombs' reagent is not always powerful enough to demonstrate weak sensitization, it is still clear that a proportion of the infants escape the effects of the disease.

With increasing degrees of sensitization the picture becomes clinically indistinguishable from physiological jaundice and all grades were seen from this to severe icterus gravis and hydrops fœtalis.

It is possible to see marked sensitization of the cells leading to severe jaundice and anæmia in a matter of hours or more slowly over one or two weeks. In some cases serious anæmia never develops. Why some infants show rapid hæmolysis and others do not is not clear. The best prognostic feature is the level of the hæmoglobin in the cord blood. As Mollison has shown, where this exceeds 14 grammes%, severe anæmia is unlikely, while if below 14 grammes% transfusion will almost always be required.

The degree of anæmia depends upon the capacity for regeneration and the rate of hæmolysis, both of which factors show considerable variation from case to case. It is still not clear why hæmolysis takes place as it is possible for sensitized cells to remain in circulation for long periods without destruction or to disappear very rapidly. *In vitro*, experiments show that complement may assist hæmolysis but that, even so, the rate is very slow.

A further matter that is little understood is the degree of jaundice resulting. This appears to depend upon the relative rates of hæmolysis and of elimination of bilirubin by the liver. The liver in the young child has a poor excretory capacity particularly in the premature infant. In the more severe cases it shows enlargement and marked extramedullary hæmopoiesis and has often been subjected to a severe degree of anæmia.

In considering the problem of kernicterus, further complexity is introduced since some of the most severe cases of jaundice show no significant degree of anæmia and yet have sufficient cerebral damage to cause death.

The cause of the damage to the brain is not clear but it is generally thought that the bile pigment is not directly responsible but is deposited in damaged tissue. Prompt replacement transfusion does not prevent it and it seems probable that the damage occurs in the antenatal period. I think that it is probably due to a direct action of the antibodies and that this hypothesis seems reasonable since once the red cells are saturated with antibodies, the free antibodies in the blood stream would, by virtue of the arrangement of the fœtal circulation, be chiefly delivered to the brain and the liver, which organs are most commonly affected after the blood.

Of the other variables which make the understanding of the disease difficult, the most interesting is the occasional variation from pregnancy to pregnancy where one sees infants with the same Rh gene subjected to the same or more powerful antibodies, and yet the later pregnancy will sometimes be less severely affected.

In conclusion, one must remember that although much progress has been made in the treatment of the disease in the live-born infant and in the recognition of its various manifestations, there is, as yet, no satisfactory method of helping the infant before birth and that much more has still to be learnt about the mechanism by which the antibodies produce their effects.

Dr. Dorothy H. Heard (*Department of Pathology, Cambridge*): When we were looking for an experimental animal to use for the investigation of hæmolytic disease of the new-born, we heard from Professor Nachtsheim (Professor of Genetics at the Kaiser Wilhelm Institute in Berlin) that he had by chance found a stock of rabbits some of whose young were born dead or moribund showing marked œdema. He considered that the condition was analogous to hydrops fœtalis in infants caused by hæmolytic disease of the new-born (Nachtsheim and Klein, 1947). In collaboration with Dr. Peter Dahr preliminary serological investigations were begun.

However post-war conditions in Berlin made it difficult for Professor Nachtsheim to maintain his stock of experimental animals and he sent some of these rabbits to Cambridge for safe keeping and for further investigation.

The rabbits were mated and the red cells of all baby rabbits were tested for sensitization by maternal antibody using goat anti-rabbit globulin serum. The does' sera were also tested for an antibody to the red cells of the buck to which they had been mated.

No antibodies were detected by these methods after three pregnancies. Accordingly 19 does were injected with whole blood from bucks to which they were later mated. The experiment was repeated using the same rabbits.

The final results were that 9 does formed antibodies in their sera. 6 of these antisera directly agglutinated the appropriate red cells but in 3 cases antibodies were demonstrated only after using an indirect sensitization test. 4 of the does who formed antibodies in their sera had between them 7 litters in which the red cells of young, inheriting a paternal antigen incompatible with their mothers' antiserum, reacted positively to a direct sensitization test. Nevertheless even the offspring whose red cells reacted positively appeared clinically normal. A proportion of the young were killed when three days and twenty-four days old and hæmatological and histological examinations were made (Heard, Hinde and Mynors, 1949).

The conclusion reached was that maternal iso-antibody may be attached *in vivo* to the red cells of baby rabbits which have inherited a paternal antigen against which their mother has produced an antibody and that this happens without affecting the baby rabbit clinically. It is not yet certain whether the antibody passes to the baby by way of the placenta or the colostrum or both. There is no more than an indication that this sensitization is accompanied

by any derangement of the hæmopoietic system or lesion of any other tissue and, from the results of this experiment, the variations between animals showing *in vivo* sensitization of their red cells and normal animals can be explained as lying within the physiological range.

These findings support the possibility that red cells can be sensitized *in vivo* without affecting the physiological function of the red cells or the individual. The reason that these animals did not show any marked pathological changes may very well be related to the active and immature hæmopoietic system the baby rabbit has at birth.

Dr. Lavinia S. Mynors (*Department of Pathology, Cambridge*): The sequel to the rabbit investigations described by Dr. Heard was the attempt to reproduce the syndrome of iso-immunization of pregnancy in the guinea-pig. This animal seemed likely to have two advantages over the rabbit in its longer gestation period and the greater maturity of its erythropoietic system at birth. The experiments have been on the same lines as those just reported. 12 guinea-pig does were mated, and injected during pregnancy with the blood of the buck to which they were mated. Their offspring were examined for anæmia, and for evidence of sensitization of their red cells by maternal antibody, and the ante-partum and post-partum sera of the does were examined for antibodies to the bucks' cells. No abnormality or sensitization was discovered in the baby guinea-pigs, and no evidence of an antibody in the sera of the does.

A further attempt to produce iso-antibodies was made with a series of 25 guinea-pig does, each receiving two courses of injections of blood from a panel of 25 guinea-pig donors. Each received contributions from 10 or more donors, and up to 4 injections from the same donor. Again no trace of antibody was discovered in the post-inoculation sera. All these guinea-pigs have now been mated to bucks from whom they have already received blood: their families are not yet born. The experiment is not complete until these offspring have been tested for evidence of sensitization and anæmia, and the ante-partum and post-partum sera of the does examined for antibodies to the bucks' cells, but we can say at this stage that there is no reason to think that we can produce a hæmolytic syndrome in guinea-pigs by this technique. Not only this, but we have produced no antibody at all, in spite of these repeated injections of foreign blood. Although other workers have reported failure to demonstrate normal guinea-pig iso-antibodies, they have not attempted, as far as we have ascertained, to produce immune iso-antibodies by the methods we have been employing.

Dr. J. M. Alston: Dr. Mollison has told us that Dr. Diamond in Boston is less satisfied than formerly with the benefit of inducing labour early as a means of treating hæmolytic disease in erythroblastotic infants. Has Dr. Mollison been able to make up his mind about the benefit of exsanguination transfusion of the newly born infants?

Dr. P. L. Mollison replied that he thought there was no doubt that exchange transfusion was a good method of treatment and that it had certain practical advantages. However, he did not consider that its ability to lower mortality and morbidity had yet been decisively demonstrated. What was needed was a controlled trial in which simple transfusion and exchange transfusion were given equally early to cases chosen at random. Such a trial was now in progress.

Dr. A. E. Mourant: Dr. Coombs referred to the question of the position of hæmolytic disease in the scheme of Nature. I cannot suggest any function which is useful but as the instance of mules shows, where 10% of the young die of the disease, it must have some effect in perpetuating the differences between varieties within a species, once these varieties have been set up by breeding in isolation: it will thus tend to lead to the development of new species. Its effect is certainly less in this respect than that of cytological barriers to interbreeding but it is nevertheless probably significant.

With regard to the possible presence of the D antigen in primates other than Man, it does not necessarily follow that it is absent from all their tissues because their red cells fail to be agglutinated by the corresponding hæmagglutinin, or even because the red cells fail to absorb the hæmagglutinin. The presence of a hæmagglutinogen in the body though not in the red cells is illustrated in the case of a number of species of monkeys among which there is a reciprocal relation between the presence of the A or B antigen in the saliva and the corresponding agglutinin in the serum. It is certain that a common antigen or similar antigens are present in the red cells of *Macacus rhesus* and of most human beings. In 1933, long before the discovery of the Rh factor as such, Buchbinder claimed to have found such a substance (which he thought to be present in all human beings) which was alcohol soluble and thermostable. These findings with regard to its properties are of interest in relation to the much disputed existence and properties of the Rh hapten.

REFERENCE

BUCHBINDER, L. (1933) *J. Immunol.*, **25**, 33–59.

Dr. G. Fulton Roberts: Some of these problems might be solved by investigating the variation in degree of antigenicity in red-cell substances. Some red-cell antigens are more potent than others (e.g. D more than C, C more than E). The D^u system shows a variation in antigenic reactivity *in vitro*. Here the various cell samples contain an antigen apparently recognized by the anti-D antibody but the reactions vary in strength, in the number of anti-D sera which are effective, and in reactivity with different types of test employed. Such intragroup variations appear to be constant and heritable. Similar variations in reactivity of cell samples from different animals in one species with an agglutinating antiserum are known.

If it could be shown that such *in vitro* variations were also operative *in vivo* both in terms of immunizing power and of reactivity, it might be possible to account for such anomalies as: (*a*) the discrepancy between incompatible matings and the incidence of the disease, (*b*) not only those mild cases in which the mother is sensitized and the infant unaffected but also the rare but very remarkable cases of healthy incompatible infants born to a mother who had previously delivered several severely affected offspring (unfortunately in none of the published accounts of the latter is the result of the Coombs test given) and (*c*) the observations that transfused cells which become sensitized in some cases survive normally and in other cases are rapidly destroyed.

Section of Endocrinology

[*November* 23, 1949]

Three cases shown by R. D. LAWRENCE, M.D.

Introduction.—It is well known from experiments on animals that, apart from pancreatic insulin, hormones from other glands play an important part in the total regulation of the blood sugar and the production of experimental diabetes. From these experiments it seems clearly established that:

(1) A centre in the hypothalamus, the area from which nerve impulses flow mainly to the pituitary, has replaced the old puncture centre of Claude Bernard in the floor of the fourth ventricle as the site of puncture diabetes.

(2) From the anterior pituitary itself hormones can be extracted which variously affect carbohydrate metabolism: (*a*) a glycotrophic hormone which, though not itself hyperglycæmic, counteracts insulin hypoglycæmia; (*b*) the adrenocorticotrophic hormone, ACTH, which, through the adrenal cortex, affects carbohydrate metabolism. Its recent use for rheumatoid arthritis has produced a condition like Cushing's syndrome; (*c*) Young's diabetogenic principle from the anterior pituitary which causes permanent diabetes in adult dogs by ultimate destruction of the islets of Langerhans. Perhaps this is closely allied with the growth hormone of Evans which in its purest form also appears to be diabetogenic.

(3) An excess of thyroid hormone empties the liver and the heart of glycogen and promotes a temporary failure to store sugar as glycogen.

(4) The adrenal cortex plays an important part in prolonged blood sugar regulation and the medullary extract adrenaline has a brief but long-established effect in produced brief hyperglycæmia.

When we turn to apply these fairly clear animal experiments to various types of human disease called "diabetes" and characterized by hyperglycæmia many clinical problems remain unintegrated. I have seen—apart from acromegaly, Cushing's syndrome and pheochromatoma — diabetes develop in Fröhlich's syndrome in eunuchism and combined with Addison's disease. Examples of some of these are demonstrated.

I.—Diabetes Mellitus with Obesity and Acromegaly.

Mrs. E. S., aged 53; a housewife with 6 children.

Past history.—She has had no serious illnesses.

Family history of obesity but no diabetes mellitus. Her paternal grandmother weighed 22 st. and a nephew weighs over 20 st.

History of present condition.—Patient was quite normal until after the birth of her last child at the age of 38, at which time she weighed 10 st. 13 lb. Her weight then began to increase and by 1940 had reached 20 st. Her hands and feet were increasing in size and her hats were getting tight. She also began to have headaches. About May 1948 she began to feel thirsty and had some frequency of micturition. She was seen by R. D. L. in July 1948 with symptoms of thirst, frequency, lassitude, genital pruritus and headache.

On examination.—Grossly obese; weight more than 20 st. Her appearance suggested some degree of acromegaly. The skin below the knees was markedly thickened and inelastic. Cardiovascular system: Heart enlarged clinically; B.P.170/100. Examination of respiratory and central nervous systems revealed nothing abnormal. Urine: 3%-4% sugar. Blood sugar at 10 a.m. was 234 mg.%.

Treatment.—Restriction in carbohydrate intake to 80 grammes per day and some restriction in intake of fats. She responded well and three weeks later her urine

contained neither sugar nor ketone bodies, blood sugar was 160 mg.% and thirst and frequency had lessened.

February 1949: The diabetes remained under good control and she had lost over 1 st. in weight. She complained that her feet and hands were still getting bigger.

Investigations.—X-rays: Bones of skull vault and base excessively thickened, hyperostosis very marked in inner tables of frontal bone. Pituitary fossa symmetrically enlarged. Eyes: Presbyopic. No diabetic retinopathy. Discs and vessels normal. Visual fields normal. V.R. less than 6/60, V.L. 3/36.

November 1949: Diabetes under good control; no sugar or acetone in urine. Blood sugar 167 mg.%. Weight more than 20 st. No change in her condition but axillary and pubic hair sparse and fine.

Dr. Raymond Greene: I think that this is a case of Morgagni's syndrome which has previously been reported in association with diabetes mellitus and acromegaly. The complete triad of obesity, hypertrichosis and hyperostosis frontalis interna is present, together with the commonest symptom of headache.

It is difficult to explain the simultaneous occurrence of all these abnormalities. In a similar case of my own the most prominent feature is the headache. Recently Dr. Colin Edwards showed to the Society a patient with hyperostosis frontalis interna who was operated on by Mr. L. C. Oliver (*Proc. R. Soc. Med.*, **43**, 251). He had found the dura attached to the frontal bone in the pits between the bosses and had freed it. The patient had been entirely free from headaches since the operation.

II.—Hæmochromatosis.

Retired schoolmaster, aged 71; married, 4 children.

History.—In August 1937 patient complained of marked lassitude, thirst, frequency and loss of weight, of acute onset. Urine contained sugar. Dr. Lawrence saw him in March 1938. His symptoms were still very marked and he weighed only 9 st. fully clothed. Previous weight 10 st. 5 lb. stripped.

On examination.—Sallow, slaty complexion (this had never been noticed either by the patient himself or relatives) with marked wasting. Axillary hair sparse and wispy as was the pubic hair which was feminine in distribution. Abdomen: Enlargement of liver down to umbilicus, firm and nodular. The cardiovascular and respiratory systems appeared to be normal.

Central nervous system: Some diminution in knee-jerks (jerks only just present with reinforcement). Eyes myopic. Some "dust" in left lens. Urine: Sugar +++. No ketone bodies. Blood sugar 250 mg.%.

Treatment.—He was stabilized on 20 units protamine zinc insulin per day; carbohydrates restricted to 120 grammes per day. Rapid improvement with loss of symptoms and marked gain in weight.

In September 1938 he was taken off insulin and his diet was increased to 150 grammes carbohydrate per day. On this he remained sugar-free until he developed an acute tonsillitis in January 1939 and had to take insulin again. He has remained well and active but has needed a slight and gradual increase in insulin to maintain good diabetic control.

November 1949: Now active and well; appetite good; digestion good. Weight 10 st. 13 lb. (clothed).

On examination.—Slaty pigmentation of skin most marked on face, arms and anterior surface of legs, very little pigmentation of abdomen. Pubic and axillary hair as before. C.V.S.: Hypertension. B.P. 170/95. R.S. normal. C.N.S.: Sensation normal. Arm-jerks present. Knee-jerks ± left and right without reinforcements. Ankle-jerks absent with reinforcement. Plantar reflexes both down. Pulses: Posterior tibial and dorsalis pedis pulses palpable on both sides. Abdomen: Liver edge palpable 3 fingerbreadths beneath costal margin; liver firm; spleen not felt. Eyes as before. Blood sedimentation rate 5 mm. in one hour. Hb 92%.

His diabetes remains well controlled on insulin and restricted carbohydrate diet. He is at present taking a dose of 10 units soluble insulin plus 16 units protamine

zinc insulin daily before breakfast, and his carbohydrate intake is still restricted to 150 grammes per day.

His latest blood sugar was 81 mg.% at 12.35 p.m. His second morning specimen on that day contained neither sugar nor ketone bodies and his night specimen of the day before contained a trace of sugar, but no ketone bodies.

III.—Acromegaly with Diabetes Mellitus and Idiopathic Skin Lesions.

Mrs. E. P., aged 45; married with no children.

History.—1923, at the age of 29, admitted to National Hospital, complaining of increase in weight for one year. Amenorrhœa for two years. Increase in the size of her hands. Alteration in vision for six weeks.

On examination at this time she had a typical acromegalic appearance; her visual fields showed a left temporal hemianopia up to fixation point and in the right eye constriction of the temporal field in the upper quadrant. No other abnormal physical signs. A glucose tolerance test showed:

	Fasting	Hours after 50 grammes glucose
Blood sugar, mg.%:	93	½ hr. 117; 1 hr. 148; 1½ hr. 113; 2 hr. 96

A craniotomy was performed and a tumour which presented to the medial side of the right optic nerve was removed.

Pathological report.—Adenoma of anterior lobe of pituitary the cells of which had abundant cytoplasm with enlarged eosinophil granules, but there were small areas of cells with scanty cytoplasm and without granules which resembled a chromophobe adenoma. The greater majority of the cells were, however, eosinophils. When the patient was seen in December 1933 the visual fields were practically normal.

In 1946 diabetes mellitus was diagnosed on account of moderate symptoms. Treated by some restriction in carbohydrate intake, but no insulin until she was seen by Dr. Lawrence in September 1949.

Present condition.—Typical acromegalic in appearance. Feels well apart from diabetic symptoms and periodic fits of depression. Appetite fair, bowels regular, but has periodic attacks of diarrhœa. Has not menstruated since before operation.

Complains of thirst, frequency, very marked lassitude, slight loss of weight, and skin infection.

On examination.—The cardiovascular and respiratory systems revealed nothing abnormal. B.P. 110/80. Central nervous system: Sensation normal. Knee-jerks both present. Ankle-jerks absent. Plantar reflexes down.

Skin: Numerous white pock-like marks distributed all over the body. The lesions apparently present as vesicles with surrounding erythema. The centre of the lesion becomes blackened and adherent and appears to separate from the surrounding skin at its edges, but then usually becomes infected after which the blackened area separates and healing takes place, leaving a thin white scar. The size of these varies between ¼ in. and 1¼ in.

Diabetes.—When first she was seen she had ++++sugar in both night and morning specimens and the blood sugar was 410 mg.%. She was given a mixed dose of insulin, 20 units soluble plus 20 units protamine zinc insulin, and her carbohydrate intake was restricted to 150 grammes per day. There was no great response to this treatment and the insulin was gradually increased until she was taking 80 units soluble insulin plus 40 units protamine zinc insulin. This reduced her noon blood sugar to 204 mg.%, but she was still passing +++ to ++++ sugar in her urine. Her symptoms improved. Her insulin was stopped for a few days and an insulin depression curve was as follows:

	Fasting	Hours after 20 units soluble insulin I.V.I.
Blood sugar, mg.%:	308	¼ hr. 308; ½ hr. 266; ¾ hr. 250; 1 hr. 230; 1½ hr. 206; 2 hr. 206

Following this she was put on a single dose of soluble insulin 80 units taken before breakfast. Diabetes responded well to this, her noon blood sugar being 132 and the fasting level being 240 mg.%.

Investigations.—B.S.R. 60 mm. per hour: Blood W.R. negative. Hb 88%. Leucocytes 10,500 per c.mm. Culture of pus from skin lesion yielded a heavy growth of *Streptococcus pyogenes*. Catheter specimen of urine yielded a growth of yeasts not of the *Candida albicans* type.

X-ray reports.—Skull: The pituitary fossa is markedly enlarged, and the dorsum sellæ is eroded. A thickened vault, large frontal sinuses and a large mandible make this typical of acromegaly. There has been a right temporal decompression. Feet: The terminal phalanges are markedly tufted and broadened. The bones are thickened and generally roughened with spur formation on the shafts. The ends of the bones are deformed. The changes are more marked in the hands than in the feet. Chest: The straight X-ray of the chest is suspicious of bronchiectasis. No evidence of Koch's infection.

Addison's Disease and Diabetes Mellitus.—S. LEONARD SIMPSON, M.D.

L. X., aged 20; a Naval Officer.

February 1947: Typical Addison's disease developed while serving as an officer in the Royal Navy, aged 18½. Serum sodium 302 mg.%, potassium 31·4 mg.% (very high), chloride 440 mg.%. Kepler test equivocal. X-rays revealed a healed pulmonary apical lesion (father died of pulmonary tuberculosis, aged 37). Blood sedimentation rate normal (3 mm., Westergren). Carbohydrate tolerance almost normal: 115 (fasting), 150, 160, 150, 125, 110 mg.% at half-hour intervals after 50 grammes glucose. Insulin sensitivity normal. Clinical improvement and normal biochemistry on 5 mg. desoxycortone injected daily. Subsequently maintained on an implant of 400 mg. desoxycortone.

June 1947: Weakness, thirst, polyuria; urine contained sugar and acetone. Fasting blood sugar 320 mg.%. Diabetic tolerance curve (200, 310, 350, 400, 380 mg.%). Diabetes controlled by soluble insulin 18 units morning, 16 units evening.

December 1947: 1 gramme salt daily added.

January 17, 1948: Arrived at hospital unconscious in hypoglycæmia, blood sugar 65 mg.%. Serum sodium 306, potassium 25, chloride 676 mg.%. 10 c.c. cortical extract daily. (For full history up to this point *see* S. L. Simpson, *J. clin. Endocr.*, 1949, **9**, 403.)

January 21, 1948: 300 mg. desoxycortone implanted.

February 7, 1948: Patient left hospital well and remained so in 1948. Another desoxycortone implant in October 1948, 400 mg. Changed to globin insulin 24 units daily owing to a tendency to hypoglycæmia.

June 1949: Further implant of 400 mg. desoxycortone; globin insulin now reduced to 14 units.

October 1949: Patient reasonably well but rather apathetic; well-marked pigmentation of gums and inner lip still present.

Comment.—This is 1 of 3 such cases that have come under my personal care. 17 such cases have been recorded with autopsy reports, the adrenal lesion atrophy in 12 and tuberculosis in 5; in all the pancreatic islet cells were reduced in size and stained poorly and there was an increase in connective tissue and lymphocytic infiltration. Diabetes or Addison's disease may appear almost simultaneously or the one may precede or follow the other. Where Addison's disease is superimposed on diabetes mellitus, the insulin requirements progressively fall, e.g. from 70 to 4 units daily as the adrenal insufficiency progressively increases. This adds point to the realization that in ordinary diabetes, the blood sugar concentrations are the result of a balance between subnormal insulin secretion on the one hand and pituitary and adrenal cortex diabetogenic or anti-insulin hormones on the other. since the

insulin requirement of a completely depancreatectomized (for carcinoma of the pancreas) man is in the neighbourhood of 36 units of insulin daily. The variations and instability of blood sugar concentrations in patients suffering from both diabetes and Addison's disease are extreme, even when the daily insulin requirements are small and the insulin sensitivity is great. Similar observations have been made in the case of the Long-Lukens pancreatectomized adrenalectomized animal, which is the experimental counterpart of the clinical condition described above.

Dwarfism, Sexual Infantilism, Diabetes Mellitus and Anæmia.—RAYMOND GREENE, D.M.

Miss J. J., aged 17, the younger of two sisters, the elder being normal.

She first came under observation in 1941, at the age of 8, when she was admitted to hospital in diabetic coma. She had no history of digestive disturbance, diarrhœa or any other serious illness. Nothing more is known of her condition at that time. She was treated with 26 units of protamine zinc insulin and 14 units of soluble insulin once daily, and a diet containing 200 grammes of carbohydrate. On several occasions in the next few years she was readmitted to hospital owing to attempts having been made to control her glycosuria. As she had a low renal threshold this always caused hypoglycæmia. On one occasion she became unstable owing to a severe urinary infection with *B. coli*. In 1945 her weight was 65 lb. and her height 50½ in. Hæmoglobin in July 1947 was 96%, but in October 1947 she was pale and with Hb only 63%. Treatment with iron raised the level to 75%.

She was first seen by R. G. in November 1948, being then just 16 years old. Her height was 52½ in. (upper measurement 27 in., lower measurement 25½ in., span 53⅜ in.) and her weight 65 lb. She had never menstruated. There were no signs of sexual development. Breasts, pubic hair and body hair were absent and the uterus was minute. The skin was soft and like a child's. The abdomen was protuberant and the liver edge could be felt one inch below the costal margin. Anæmia was not suspected and the blood count at that time was not done. Intelligence was good and she was earning her living as a shorthand-typist, but emotionally she was infantile. Her whole appearance and manner suggested a child of 9 or 10. The diabetes was poorly controlled. X-rays showed the bone age to be approximately 14 years. Skiagrams of the skull were normal. The follicle-stimulating hormone excretion could not at that time be measured.

Her diabetes was well controlled by a 14 line Lawrence diet (*see* Lawrence, 1950, The Diabetic Life, London, 14th Ed.) and a daily dose of 48 units of protamine zinc insulin. Thereafter she remained in excellent health for six months. Treatment with stilbœstrol and ethisterone given cyclically produced regular withdrawal bleedings, but there was no sign of breast development, no pubic hair grew and the uterus remained small. The insulin requirements were unaffected. No increase in height. Liver no longer palpable.

In May 1949 she was in her usual health, but when she reported in June she was extremely pale and dyspnœic, with œdema of the ankles, a pink smooth tongue and severe ulceration of the mouth. She had lost 4½ lb. in weight. Investigations showed that her diabetes was still well controlled. Blood count: R.B.C. 2,900,000; Hb 44%; C.I. 0·76; W.B.C. 7,000 (normal proportions). Liver not palpable. Urine normal. Serum proteins 6·5% (alb. 4·8%, glob. 1·7%). Blood urea 21%. Urea clearance normal. Fractional test meal (F.T.M.) normal. Fæcal fats: Soaps 17, free fatty acid 10·2, neutral fats 8·8; total 36 grammes %. She was given iron. A week later a blood count showed: Hb 57%; M.C.H.C. 30%. Corpuscular diameter too various for measurement of M.C.D. with a halometer, but most cells 7·8–8μ. M.C.V. 90 cu.μ. Poikilocytosis and very marked anisocytosis. There was a further improvement in the hæmoglobin level in the next month to 68%, but in the subsequent month no further improvement. Treatment with vitamin B_{12} raised the

hæmoglobin rapidly to 90%; the blood has since remained normal on a fortnightly dose of 20 microgrammes.

With the exception of a period of two months in which she was anæmic, she has been during the past year in excellent health, with her diabetes well controlled. Despite this she has not grown at all and sexual development has not begun.

Dr. Greene suggested that this was a case of ovarian agenesis. He had seen two other cases (one shown last year to the Section and one of Turner's syndrome) in which hypogonadism, dwarfism and diabetes occurred together; and he found it difficult to dismiss the concurrence as fortuitous. He had no explanation to offer of the sudden appearance of what was probably a megaloblastic anæmia.

Dr. I. H. Milner suggested that the diagnosis was a pituitary dysfunction causing dwarfism, anæmia, and even also the diabetes—occurring before puberty—and referred to the series of cases of hypopituitarism with anæmia reported by Groen, Hunter, Snapper and Witts.

Dr. Greene replied that it was usual in anæmia due to pituitary deficiency to find achlorhydria. The patient's F.T.M. was normal. He agreed that without an estimate of the F.S.H. excretion it was impossible to be certain that the ovary was primarily involved. The evidence for a megaloblastic anæmia was poor, but he drew attention to the rapid response to vitamin B_{12}.

Dr. H. Gardiner-Hill thought the whole syndrome might be explained as a case of cryptic idiopathic steatorrhœa with consequent nutritional deficiency.

Dr. Greene agreed that without a fat balance experiment this diagnosis could not be excluded, but pointed out that except for the rather large abdomen there was no positive evidence to support it. There had never been any evidence of vitamin deficiency or of deficiency of any mineral except iron. The F.T.M. was normal and there was no history of digestive disturbance.

Dr. R. D. Lawrence said he thought the whole syndrome could be explained as due to diabetes and that he would expect growth and sexual development to begin now that the diabetes was well controlled.

Dr. Greene pointed out that this condition had been fulfilled for a year without any change during that time.

Dr. Wilfrid Oakley suggested that a liver dysfunction might link the diabetes with the anæmia.

Diabetes Mellitus with Thyrotoxicosis.—I. GILLILAND, M.D., M.R.C.P.

Mrs. A. H., aged 52; housewife, with 3 children.

History.—She was found to be a diabetic during the Civil War in Spain in 1937, and control was inadequate owing to the difficulty of getting insulin. She suffered considerable privations and persecution in Spain subsequent to the Civil War until her escape in February 1948.

Four months after she arrived in this country, where her circumstances were much better than in Spain, she began to suffer from palpitations and sweating, and was nervous and irritable.

When first seen in December 1948, she weighed 5 st. 13 lb. and was obviously diabetic. Fasting blood sugar 220 mg.%. Urine (Benedict) constantly orange. An enlarged thyroid without bruit was noted. She was excitable and had a fine tremor, pulse 100, B.P. 200/100; no abnormal chest signs. She was thought to be a nervous, undernourished and poorly controlled diabetic.

She was fairly well stabilized on 36 units globin insulin and a diet of 2,091 calories, (266 g. carbohydrate, 88 g. protein and 75 g. fat). Gained 10 lb. in eight weeks. However, her nervousness and hyperactive circulation became more obvious with this improvement and her periods, which had been normal, became excessive in April 1949. In May 1949 she was admitted for assessment and treatment of her hyperthyroidism.

Condition on examination before thiouracil therapy: A restless, hyperactive person, with hot moist skin; capillary pulsation present, and a fine tremor. Sleeping pulse 120. B.P. 120/80. Fasting for a B.M.R. estimation precipitated a period of diabetic acidosis. Glucose tolerance test (fasting and half-hourly): 355, 489, 592, 592, 496, 432, 394 mg.% (Fig. 1 (1)). Blood Hb 102%. W.B.C. 8,000; Cholesterol 175 mg.%. Blood urea 42 mg.%. B.M.R. + 64%.

Radioactive iodine urinary excretion (a clearly thyrotoxic result): Hours 0–8: 8·5%; 8–12: 0·3%; 12–24: 0·5%; 24–48: 2·4%. Total 11·7% in forty-eight hours.

Methyl thiouracil 0·2 g. t.d.s. was commenced on 21.5.49 and was followed by a striking improvement. She has had methyl thiour. 0·1 gramme t.d.s. and sod. l-thyroxine 0·2 mg. since June 1949. Has gained 3 st. and her activity is now normal. The diabetes is controlled on P.Z.I. 24 Sol. 10, and a diet of 2,860 calories (carbohydrate 388 g., protein 93 g., fat 104 g.). Pulse 120. B.P. 210/80. Her thyroid has not noticeably increased in size though a great widening of her neck is now evident which her husband states is a return to her normal condition.

Glucose tolerance test at this stage (fasting and half-hourly for three hours): 335, 458, 386, 314, 270, 262 mg.% (*see* Fig. 1 (2)).

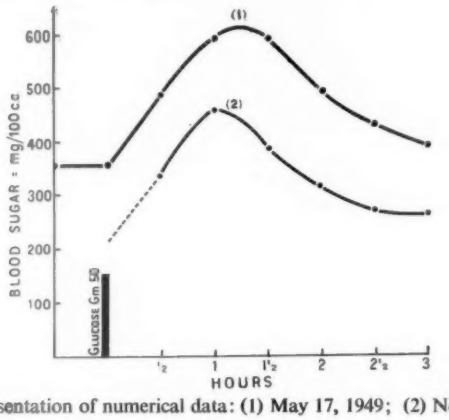

FIG. 1.—Serial presentation of numerical data: (1) May 17, 1949; (2) November 17, 1949.

[*January* 25, 1950]

Hormone Assays on Body Fluids

PRESIDENT'S ADDRESS

By A. S. PARKES, M.A., Sc.D., F.R.S.

I APPRECIATED very much the honour of being elected President of the Section, partly because it really is an honour, and partly because it is, I imagine, somewhat unusual for a biologist to become President of a Section of this Society. I feel, however, that the event has a wider significance than my personal concern. For the last three years, since its beginning in fact, I have been Chairman of the Society for Endocrinology, and the fact that for a brief period the chief offices of both the Section and the Society are occupied by the same person, must be a cause for satisfaction among those who have at heart the progress of endocrinology. The Society and the Section were inaugurated at about the same time, and a minority view that this twin birth was overdoing things has not been substantiated by events. As expected by most of us the two organizations have turned out to be complementary, not conflicting. The Society is concerned mainly with laboratory work relating to vertebrates in general, and in the eyes of a biologist man is just another vertebrate. In these circumstances the Society naturally has a membership consisting largely of biologists and biochemists, though the number of medical members is gratifyingly large. The Section, by contrast, deals mainly with work pertaining to man, laboratory animals coming into the picture largely as tools. Members of the Section could hardly be expected to give their undivided attention to a paper dealing primarily with, say, the plumage of birds, and some members of the Society would certainly feel out of place at a meeting at which patients were shown. There is thus ample room for both of the organizations acting individually within their particular spheres. But I would go further. Not only is there ample scope for both organizations acting independently, there is vital scope for their co-operation. Few

would dispute that two of the best meetings held by either were the two joint meetings held in the last two years. We should look forward, therefore, not only to an increasing emphasis on the individual character of the two organizations, but to an increasing co-operation between them. For this reason I am especially pleased to have been elected President of the Section while still Chairman of the Society. We may hope that one day, not too distant, the Society will return the compliment and elect as its Chairman the President of the Section.

To-day, I want to talk about the estimation and significance of hormones and their derivatives in body fluids, on the one hand to add to our knowledge of the working of the body, and on the other hand as an aid to diagnosis and therapy of disorders of endocrine organs.

I was led to my choice of subject by two considerations. Firstly, of all endocrinological problems, this is the one that most closely brings together the biologist and biochemist with medical men. Secondly, it is one which has been of pressing interest for many years, and promises to continue so. Obviously it would be impossible, or even improper, for me to attempt to give a complete and coherent picture of this vast field. What I want to do is to make a series of rather general points illustrated by discursions into particular matters. My text, if I have one, is "Back to Blood".

Much of what I have to say will sound elementary, but in a complicated problem like this there is much to be said for keeping a firm grasp on fundamental principles. A hormone by its classical definition must appear in effective concentration in the circulating blood. In theory, therefore, it should be possible to find out its normal effective level in the blood, and then proceed to the diagnosis of hypo- or hyper-states according to the levels found in particular cases. This simple idea is obviously subject to easily foreseeable complications. The hormone might circulate in a form in which it is inactive, it might be present in amounts so minute as to be undetectable, it might appear cyclically, or transiently, or variation in sensitivity of the end-organ might be an important factor in determining the effective level in the blood stream. Nevertheless, it is my belief that the key to the problem of effective hormone levels must be sought in the circulating blood. Some of you may remember the work of R. T. Frank in New York, who, twenty-five years ago, immediately following the work of Allen and Doisy, demonstrated the presence of œstrogen (female sex hormone as it was then known) in the circulating blood of woman. Frank and his collaborators followed up this observation with a great deal of work on blood-œstrogen levels under different conditions. Their methods were inadequate to say the least, and they made little impression on the biological or clinical worlds. Looking back, however, Frank's basic idea seems to me to have been right, and he deserves recognition as a pioneer.

Shortly afterwards, œstrogen was discovered in the urine of women and in the blood and urine of men, and then in enormous quantities in the urine of pregnant women. The latter finding was particularly disconcerting, as at that time œstrogen was thought to be connected essentially with the follicular phase of the cycle, and the administration of exogenous œstrogen was already known to terminate pregnancy in certain laboratory animals. These discoveries led to dramatic advances in the chemical field, but confused the biological picture and diverted attention from the circulating blood. The same is true of Zondek and Aschheim's later discovery of large amounts of gonadotrophin in pregnancy urine. In consequence of these diversions, and because of the fact that urine is easier to obtain than blood, by far the greater amount of work on so-called hormone estimations has been carried out on excretion products. This state of affairs is not necessarily very satisfactory, and it can be argued that the discoveries of Zondek and Aschheim, spectacular and valuable as they were, diverted biological thought and research away from the study of the endocrinological integration of normal animals, including man. It is difficult, for instance, to believe that the small amounts of œstrogen found in the urine of the males of many species, and in the urine of stallions in huge amounts, are anything more than an incidental waste

product or bye-product without physiological function in the reproductive processes of the animal itself. The prostate gland, and particularly the uterus masculinus of the stallion show no sign of œstrogenization. Moreover, there is good reason to believe that different hormones may have similar excretion products, while others have no excretion product at present recognizable as such. The diagnostic and biological significance of hormone assays on urine must, therefore, be considered in the light of all these complications. I am not competent to speak of clinical matters, but in laboratory work one has constantly to be on guard lest a routine procedure degenerate into a mere ritual.

In saying this, I must not give the impression that work on the hormones of the circulating blood is negligible. There is, for instance, a good deal of information about the blood concentration of œstrogen and gonadotrophin during normal human pregnancy. Estimations of this kind are inherently more difficult on the non-pregnant subject because of the small amounts of material involved, and much of the work carried out on the levels of reproductive hormones during the menstrual cycle is for the most part not very convincing. The difficulties are largely those of technique. Blood samples must be strictly limited in amount; and, at best, they contain only small amounts of active substance in a highly complex medium. In the circumstances the problem turns on precision of extraction where this is attempted, and on the sensitivity and specificity of the chemical or biological assay method. It is most significant to note that important advances have recently been made on all these fronts, and that in general a back-to-blood movement is gathering momentum. It is encouraging to see that chemical methods for the estimation of steroids, especially progesterone, in blood have recently been worked on by Butt, Morris and Morris (1949), and it may be recalled that Reynolds and Ginsburg in 1942 made an early investigation of this field. It is to be hoped that further attention will be given to this problem. Of all the hormones of interest to the student of the reproductive processes, progesterone has been the most elusive in body fluids. This fact is due to the comparatively large amounts required for the usual biological test and to its apparent absence from urine at all stages of the reproductive cycle. In consequence, a great deal of attention has been given to the inactive excretion product of progesterone, pregnanediol, which has become one of the most investigated of all urinary steroids. The estimation of pregnanediol as an indication of luteal function has two serious disadvantages: it is difficult to measure in small amounts, and it may be derived from other sources than progesterone. I am sure that many of those actively concerned in this work, including my very old friend and collaborator Professor G. F. Marrian, will agree if I say that much of the work would not have been carried out had there been available a simple method of estimating progesterone in circulating blood.

Biological methods, about which I am more competent to talk, are also being improved. It is the general rule that methods based on local application of the active substance to the responding tissue are much more sensitive than those depending on systemic application. The injection of prolactin into the wall of the pigeon crop, the inunction of androgen to the capon comb, and the intravaginal administration of œstrogen, all provide illustrations to this general rule. Local administration also has the advantage that it distinguishes between immediately active substances and those which require modification in the body before becoming active. Thus, Emmens separated synthetic œstrogens into two categories, real œstrogens and pro-œstrogens which were activated in the body. By means of intravaginal assay, Markee and Berg (1944) were able to study the blood concentration of œstrogen during the normal menstrual cycle. Their results were concordant with, but better defined than those of Fluhmann and others, and showed a much increased concentration of œstrogen about the time of ovulation and during the first part of the luteal phase. It is to be supposed that many, or even most, of Markee and Berg's subjects were having normal ovular cycles, and the results imply that œstrogen withdrawal is a factor in the initiation

of menstruation even in the presence of a corpus luteum. In anovular cycles it may well, of course, be the chief factor. We may look forward to further progress, especially along the lines of the work of Szego and Roberts (1946, 1947) who found that in normal and pregnant cows, normal and gonadotrophinized rabbits, and in pregnant women, the blood œstrogen was in two forms, free and protein-bound, in the ratio of about one-third and two-thirds respectively.

Pursuing further this matter of the biological assay of hormones in circulating blood, we come again to progesterone. I have referred a few minutes ago to the difficulties of estimating this hormone in body fluids, and it is encouraging to be able to point out a very substantial advance on the biological side in the last two or three years, and to provide another example of the value of local administration in assay work. Local administration is obviously most easy where the organ in question is accessible from the exterior of the animal. It is, therefore, more difficult to evolve such a method for progesterone, which gives specific response only in the uterus. However, McGinty, Anderson and McCullough (1939) found that the uterus of the œstrogen-sensitized rabbit responded typically to minute amounts of crystalline progesterone (0·0005–0·005 mg.) placed directly into the lumen. This was confirmed by Haskins (1939) who further found that a positive reaction could be obtained in such a test by 0·2 c.c. of serum from a pregnant guinea-pig. The most interesting work of this kind, however, is being developed by Hooker and Forbes in Yale. These authors have evolved a microbiological test for progesterone which depends on the local administration of progesterone or the material for test, into the lumen of an isolated segment of the uterus of the ovariectomized mouse. A positive reaction is indicated by characteristic changes in the stromal nuclei of the endometrium. The sensitivity of the test is such that the minimum effective dose of progesterone is 0·0002 μg., one five-millionth of a milligramme (Hooker and Forbes, 1947). The sensitivity is remarkable when it is considered that about 0·5 mg. is required for the standard Corner test, or the deciduoma reaction in the rat. The Hooker-Forbes test for progesterone must, in fact, rank high among the most sensitive biological tests. The test, moreover, is highly specific (Hooker and Forbes, 1949*b*), a wide range of biologically active and inactive steroids having been found to give negative results. Of the substances tested only pregnanediol in a dose 30,000 times greater than that of progesterone gave a dubious positive response. The test has certain disadvantages; it is time-consuming, and the end-point of the reaction is not very sharp. These, however, are administrative difficulties rather than biological ones. By the use of this test, Hooker and Forbes (1949*a*) found blood progesterone levels of between 4·0 and 8·0 μg. per ml. of whole blood during phases of luteal activity in rabbits, mice, a monkey, and an 8 weeks' pregnant woman. All the active material was in the plasma, 90% being free and 10% protein-bound, fractionation being accomplished by the methods employed for blood œstrogen by Szego and Roberts (1947). The free/bound ratio appears to be different from that found for œstrogen, since over 60% of blood œstrogen is found in combination with protein. Hooker and Forbes consider that protein binding is a means of hepatic inactivation of progesterone in mice. Incidentally, it would be interesting to know whether humans suffering from liver damage show signs of hyper-progesteronism in the same way as they are said to show signs of hyper-œstrogenization. The fruits of the work of Hooker and Forbes are only just beginning to appear and we may look forward confidently to further interesting results. In the meantime we may note that variation in blood progesterone levels have been noted during the laying cycle in domestic fowl. As is usual in this kind of work, Fraps, Hooker and Forbes (1949) have since recorded the occurrence of comparatively large amounts of progesterone in the blood of cockerels, an intellectual dilemma reminiscent of that caused by the discovery of lactogenic hormone in the pituitary of fishes.

I come now to my last point. There has recently been much discussion as to the best way of arranging for and organizing work on hormones and their derivatives in

human body fluids, and I want to summarize some general considerations as they appear to me. In doing so I must say immediately that I have had the benefit of discussions with various members of the Section who are actively interested in the matter, notably Dr. A. C. Crooke, Professor C. H. Gray, Dr. E. F. Scowen, Dr. Russell Fraser and Professor G. F. Marrian.

Let us consider first the pros and cons of a central assay laboratory, as a common facility for hospitals, and having no control or power of selection of material sent in. If it could be made to work such an organization would have certain advantages, standardization of methods, concentration of equipment and personnel, &c., but the disadvantages are overwhelming. It could deal with little but routine work and might well be swamped under a mass of indifferent material. It would probably degenerate into a slot machine, which would be demoralizing for staff and clients alike. Worst of all, however, it would do nothing to foster the contact between clinicians and laboratory workers which is necessary if they are to appreciate each other's problems and limitations. On balance, I feel strongly against any attempt to set up such a central laboratory.

Dealing now with organizations designed to advance knowledge, as well as to carry out a certain amount of routine work, I think one must be quite clear as to the objective in view. In other words, one must be clear as to whether the aim is to advance knowledge along whatever promising line may emerge, or to advance knowledge in some particular direction, for example, in a clinical direction. For some three years before the war there was a small unit consisting of two biochemists and a biologist working at Hampstead. The immediate object of this unit was to tidy up, biologically and biochemically, what appeared from the literature to be a very untidy situation. To produce quickly knowledge of immediate clinical usefulness was a minor object. Experience with this unit showed some of the inherent difficulties; one had constantly to beware of the temptation, or even the pressure, to fritter away time and resources in all kinds of side issues and odd assays. This unit, in a somewhat isolated Institute devoted entirely to research was, of course, largely dependent for the supply of material on the good nature and helpfulness of clinicians to whom we could offer little in return. At the end of three years' intensive work we were still unable to tell with certainty whether any particular sample of urine had come from a man or a woman. The unit, however, did much fundamental work, the main conclusions of which were summarized by Dr. Callow to this Society in 1940. The chief result of immediate clinical usefulness was the recognition of isodehydroandrosterone as the source of the extraordinary androgenic activity of the urine in certain types of adrenal tumour, and the application of this finding to diagnosis, by Crooke and Callow (1939).

For the purposes for which it was started the unit at Hampstead was well situated. Where, however, the main object is the advancement of knowledge in a clinically useful direction, I feel sure that the biochemists and biologists must be in close touch with the clinicians; in other words the laboratory workers must be brought to the clinical material, not the material to the laboratory workers. There are, at present, several hospitals in which biochemists and biologists are working in the closest collaboration with clinicians on endocrinological problems, whether or not the organization actually has the title of an endocrine unit. This seems to me to be a satisfactory state of affairs and one which should be pursued to the limit of its usefulness. What this limit is, namely what is the optimal concentration of endocrine units, I am not in a position to say. It is, however, easy to see that every unit cannot be all-embracing. The range of facilities required for a complete organization is steadily increasing, and now includes biological tests for androgens, œstrogens, progesterone, corticoids, gonadotrophins, thyrotrophins, adrenocorticotrophins, and others; and on the chemical and physical side, tests for 3-, 17- and 20- ketosteroids, œstrogens, pregnanediol, and others, as well as measurements of radio-activity and many ordinary biochemical tests. All this implies great elaboration of staff and equipment. And the

requirements are constantly increasing. Allow me to quote from a review by Dobriner (1948), of the work carried out by him and his colleagues at the Sloane Kettering Institute for Cancer Research, New York, on the steroids of human urine, with special reference to substances possibly indicative of early cancer:

"The steroids, after hydrolysis of the conjugates, have been separated into several fractions and we have examined thus far in detail the α- and β-ketones. Up to the present time we have been able to isolate over 45 steroids from these fractions. Since these steroids are closely related chemically and differ but little in their properties, we found it necessary to employ a physico-chemical method of separation. This technique, chromatographic adsorption analysis . . .

"When very closely related substances are present 'fractional chromatographic analysis' is necessary. This involves several chromatograms. The procedure is reminiscent of a systematic fractional crystallization, but is far more efficient, especially with respect to recovery of material. When applied to the α-ketonic fraction from a single specimen of urine, these procedures result in the accumulation of from 500 to 3,000 separate fractions, from which the individual steroids are obtained. A quantitative measure of these constituents is achieved by application of the Zimmermann reaction. Each individual steroid is then isolated and characterized in the usual way by determination of melting point, specific rotation, and, as will be discussed below, its infra-red absorption spectrum. Confirmation of the structure of the compound is obtained by the preparation and characterization of suitable derivatives. Wherever possible, the substance isolated has been compared with an authentic sample.

"In the course of this study a total of 42 apparently homogeneous and non-identical substances have been encountered. 26 of these have been fully characterized and identified; the other 16 are characterized and are probably new ketosteroids. 11 of the fully identified compounds have been isolated from urine by previous investigators; thus, 31 fully or partially characterized substances have not been encountered previously in human urine."

Dobriner's laboratory is enormously impressive, and obviously he and his colleagues are obtaining information of the greatest scientific interest. Whether it is of equal clinical importance I do not know. My point is that a set-up of this kind cannot be expected in every endocrine unit, and the same applies in a lesser degree to other complicated physical and chemical apparatus. For this, and other reasons, it seems that each unit, apart from carrying on whatever amount of routine work may be thought desirable and possible, should select and concentrate on a small number of problems for intensive investigation. This idea, which is already largely being acted upon, implies that there should be close contact and consultation between the various units, so that the total resources may be brought to bear in the most effective manner. Consultation is also desirable for the standardization of routine methods which, due to constant slight modifications which are not necessarily improvements, tend to get inco-ordinated and to complicate the comparison of results. I incline to the view, therefore, that if any central body such as the Medical Research Council is to take a general interest in this matter it should be on the lines of supporting individual units and facilitating their mutual co-ordination, rather than on the lines of providing a central laboratory for routine assays. And, I hope that any such body will take as its maxim "Back to Blood".

Section of Anæsthetics

President—GEOFFREY ORGANE, M.D., F.F.A.R.C.S.

[*December* 2, 1949]

Males and Females as Anæsthetic Risks

By TORSTEN GORDH, M.D. (*Stockholm*)

THIS is a statistical analysis of personally conducted anæsthesias in cases of gall-bladder surgery and gastric resections during the five-year period 1944/48. The material comes from the University hospitals (Karolinska Sjukhuset and Serafimerlasarettet) and private clinics in Stockholm. It is thus strictly personal material from the anæsthetic point of view, and from the surgical side it deals with well-defined groups of operations, where both indications and technique have been uniform. It includes most of the serious cases at the hospitals, and the average age is exceptionally high, since the worst risks and the oldest patients have been handled by the most experienced anæsthetist. The operations were performed by experienced surgeons : 80% by professors in surgery, 15% by assistant professors and 5% by residents.

The anæsthetic record card introduced by Nosworthy and modified according to local requirements was used for the purposes of this study. The judgment of the pre-operative risk, the choice and conduct of anæsthesia and the post-operative follow-up have been made by the author in every case and with the idea of a later statistical investigation.

428 *cholecystectomies* (Tables I–V).

In these tables the incidence of post-operative pulmonary complications is shown to give a general view of the post-operative course. Both minor and major complications are

TABLE I.—CHOLECYSTECTOMY (428 CASES)

Pathological condition	Operation performed	Total cases	Deaths	Mortality %
Cholecystitis and cholelithiasis	Cholecystectomy with or without cholangiography, or exploration of the common bile duct	351	5	1·4
Cholecystitis	Cholecystostomy	4	0	0
Cholecystitis complicated by stones in the common bile duct with or without jaundice	Cholecystectomy + choledochotomy with or without cholangiography or choledochostomy	54	1	1·8
Stones in the common bile duct recurring after, or overlooked at, a previous cholecystectomy	Choledochotomy with or without choledochostomy	19	0	0
		428	6	1·4

included, and were as follows : cough (6), bronchitis (6), atelectasis (3), bronchopneumonia (12) and pleuritis (1). Table II shows the age distribution. The majority, 61%, are over 50 years of age. The differences in pulmonary complications are not statistically significant for any age.

TABLE II.—AGE DISTRIBUTION

Age	Total cases	Post-operative pulmonary complications %	Deaths	Mortality %
21–30	32	0	0	0
31–40	43	2·3	0	0
41–50	89	2·2	0	0
51–60	132	8·3	2	1·5
61–70	104	10·6	4	3·8
71–80	28	3·5	0	0
	428			

TABLE III.—PHYSICAL STATE

Risk	Total cases	Post-operative pulmonary complications %	Post-operative circ. complications %	Deaths	Mortality %
I	98	2·0	2·0	0	0
II	228	6·1	2·7	2	0·8
III	93	9·6	8·9	3	3·2
IV	9	11·1	22·2	1	11·1
	428				

Table III shows the distribution according to the patient's physical condition. The grading is based on the physical state and the usual four-risk grouping is used. In judging post-operative results a more accurate view is obtained by grading the patients by physical state or risk. A qualitative presentation also gives more information than a purely quantitative one, as in Table I. Providing the anæsthesia and operation are " lege artis " performed there ought to be no mortality in risk I, whereas a mortality of 20% in risk IV may be considered reasonably normal.

TABLE IV.—ANÆSTHESIA

Anæsthetics: Primary and secondary	Total cases	Complications during anæsthesia: Resp. %	Circ. %	G.–I. %	Post-operative resp. complications %	Deaths	Mortality %
Spinal + + i.v (230) + N_2O (130)	236	2·1	34·2	7·6	5·5	5	2·1
Intravenous + + N_2O (152) + local (155) + curare (127) + C_3H_6 (20)	169	20·6	17·1	0·6	7·1	1	0·5
Ether	23	8·7	26·0	8·7	4·3	0	0
	428						

The material is presented according to anæsthetic used in Table IV. Spinal anæsthesia was the primary method in 55% and intravenous anæsthesia in 40%. Ether was used in only 5%. The complementary secondary anæsthetics are recorded in the table. A special study of the course of anæsthesia showed that only 60% were considered satisfactory. Exacting criteria have been used and all deviations from the normal physiological state have been recorded. Complications occurred mainly from the respiratory, circulatory, and gastro-intestinal systems. The main *respiratory* ones were laryngospasm, bronchospasm, obstructed airway from other causes, and respiratory arrest. These were most common with intravenous anæsthesia, 20·6% against 2·1% with spinal anæsthesia. The *circulatory*

complications were respectively 17·1% and 34·2%, being most common with spinal anæsthesia. They were noted as severe fall in blood pressure (to 70 mm.Hg or below), tachycardia, and arrhythmia. *Gastro-intestinal* troubles such as vomiting, hiccough and nausea were also commoner during spinal anæsthesia, the frequencies being respectively 7·6% and 0·6%, a difference which is statistically significant, as calculated by ordinary formulæ.

However, all complications during anæsthesia and operation have been treated promptly, so that the patients have left the operating theatre in the most satisfactory condition possible, as assessed by the presence of reflexes and by adequate respiration and circulation. 92% of the patients have been so wide awake that they have reacted or replied to questioning. The duration of anæsthesia and operation has accordingly not influenced the end-results in any significant way, as will be observed in Table V.

TABLE V.—DURATION OF ANÆSTHESIA AND OPERATION

Anæsthesia Time in hours	Total cases	Post-operative resp. complications %	Deaths	Mortality %
$<\frac{1}{2}$	11	9·1	0	0
$\frac{1}{2}$–1	219	6·4	3	1·3
1 –$1\frac{1}{2}$	136	5·1	3	2·2
$1\frac{1}{2}$–2	51	8·0	0	0
2 –3	11	9·1	0	0
	428			

222 *gastric resections* (Tables VI–X)

The analysis of the gastric resections is presented in exactly the same manner and in the same sequence as for the cholecystectomies. The same type of resection was performed in all the 222 cases. The post-operative *pulmonary complications* in this series amount to 13·5% and were as follows : cough (8), bronchitis (6), atelectasis (1), bronchopneumonia (14), pleuritis (1). The circulatory complications amounted to 7·2% and were noted as : severe fall in blood pressure, shock (5), internal hæmorrhage (3), thrombosis (3), pulmonary emboli (4), heart failure (1). The pathological conditions for which the operation was performed and the mortality are give in Table VI. Table VII gives the age incidence and shows that the majority of patients (53%) were over 50 years of age. In the main, the same comments may be made here as for the first group.

TABLE VI.—GASTRIC RESECTION (222 CASES)

Pathological condition	Operation performed	Total	Deaths	%
Gastric or duodenal ulcer	Gastric resection (Billroth II)	173	6	3·4
Gastric or duodenal ulcer with acute hæmorrhage		8	0	0
Post-operative jejunal ulcer		3	0	0
Perforated gastric or duodenal ulcer		6	0	0
Carcinoma		32	2	6·2
		222	8	3·6

TABLE VII.—AGE DISTRIBUTION

Age years	Total cases	Post-operative pulmonary complications %	Post-operative circ. complications %	Mortality %
20–30	16	6·2	0	0
31–40	33	9·0	15·1	2·9
41–50	58	15·4	8·6	1·7
51–60	58	8·6	3·4	5·6
61–70	45	17·4	4·3	2·2
71–80	12	0	8·3	4·1
	222			

TABLE VIII.—PHYSICAL STATE

Risk	Total cases	Post-operative pulmonary complications %	Post-operative circ. complications %	Deaths	Mortality %
I	57	11·9	5·9	0	0
II	118	11·1	8·3	3	2·8
III	38	12·0	5·1	3	7·6
IV	9	11·1	11·1	2	22·2
	222				

TABLE IX.—ANÆSTHESIA

Anæsthesia: Primary and secondary	Total cases	Complications during anæsthesia: Resp. %	Circ. %	G.–I. %	Post-op. resp. compl. %	Post-op. circ. compl. %	Deaths	Mortality %
Spinal + + i.v. (168) + N_2O (75) + ether (4)	169	2·9	25·5	29·5	14·1	7·6	7	4·1
Intravenous + + N_2O (48) + local (46) + curare (42) + C_3H_6 (3) + ether (4)	53	18·8	22·6	7·5	11·3	5·6	1	1·9
	222							

TABLE X.—DURATION OF ANÆSTHESIA AND OPERATION

Anæsthesia Time in hours	Total cases	Post-operative resp. complications %	Post-operative circ. complications %	Deaths	Mortality %
1	7	28·5	0	0	0
1 –1½	63	14·3	7·8	4	6·3
1½–2	90	10·0	6·6	3	3·3
2 –3	53	9·4	9·4	1	1·9
3 –4	9	22·2	0	0	0
	222				

Sex differences in the material (Table XI, Groups A and B).

The main causes of death in both series were : paralytic ileus (5), pulmonary emboli (2), peritonitis (3), hepato-renal syndrome (1), heart failure (1), bronchopneumonia (1), cachexia (1). The fact that all the deaths occurred in males prompted me to make a comparison of the behaviour of the sexes. Table XI shows some of the findings.

TABLE XI

Sex	Total cases	%	Average age	Average risk	Anesth. period satisfactory	Post-op. complications: Resp.	Circ.	G.–I.	Deaths	Mortality %
GROUP A.—428 CHOLECYSTECTOMIES										
M.	130	31	61	2·2	50%	11·5%	7·0%	14%	6	4·6
F.	298	69	56	1·9	65%	3·6%	3·0%	19%	0	0
GROUP B.—222 GASTRIC RESECTIONS										
M.	162	73	56	1·9	46%	15·4%	8·0%	11·1%	8	4·9
F.	60	37	54	2·2	65%	8·3%	5·0%	21·1%	0	0

In Group A, the cholecystectomies, the female sex predominates with 69%, and in Group B, the gastric resections, the male predominates with 73%. These figures are in accordance with those of other observers. But in spite of this difference the behaviour during and after

anæsthesia and operation is strikingly similar for both sexes. There are no statistical significant differences as to post-operative complications and mortality in the different age groups. The average risk varies in both groups. In Group A, the average risk for males is higher than for females, and in Group B, the opposite is observed.

If we look at the course of the anæsthesia we find that whereas for females 65% of the anæsthetics have been considered satisfactory, only 46% and 50% in the male cases have been so. We know that men are more resistant to poisons and to drugs in general, owing to their more vigorous constitution. In any case, in this material there is a statistically significant difference in the frequency of complications during anæsthesia.

As far as the post-operative pulmonary complications are concerned the difference is well known and is also statistically very evident. King found in his classical work in 1933 that the incidence of pulmonary complications among men was at least twice that among women. He designated as " bad risks " men having operations on the stomach and duodenum, gall-bladder and intestines owing to the consistently high percentage of pulmonary complications in such cases. Brock finds the same in his study in *Guy's Hospital Reports* (1936). Holmes found in his analysis of pulmonary complications in 2,064 consecutive cases (1948) that the majority of complications occurred in men. The heavier smoking by men is one explanation ; another is that in women the respiration is predominantly costal in type, so that an abdominal wound produces less reduction of respiratory exchange.

It is also a well-known fact that women are more sensitive to morphine and its derivatives than men, which accounts for the finding of a higher incidence of post-operative *vomiting* and *nausea* among women. However, the more serious complications are more frequent in men. Thus, of the 13 cases with *paralytic ileus* 11 were men, 5 of whom died of paralytic ileus. In 12 cases with hiccough there was only 1 woman. This tendency to hiccough in males is also noted during the actual operation.

It appears from this analysis that males are a poor risk in general, and are more liable to anæsthetic and post-operative complications, a fact which does not seem to be generally recognized. However, vital statistics show that the average expectation of life for a woman in the U.S.A. is five years longer than for a male. Investigations by Johnstone and Hosker (1948) show a higher mortality among males of all ages from pneumonia, bronchitis, appendicitis, peptic ulcer, &c. They conclude that the occupational differences must be an important factor in producing dissimilarity of male and female death-rates.

Allen (1934) states that " mere maleness influences unfavourably the resistance of the organism to disease at all ages". Hamilton (1948) points out that the shorter life span of males characterizes most of the species of animals so far investigated, i.e. 42 species including nematodes, molluscs, birds, insects, fish and mammals. This shows the error of assuming that the differences in modes of life and habits are a factor in the different longevity of males and females. Supported by experiments on animals and human castrates he proves that testicular secretions contribute to the lesser viability of males. In addition to specific actions upon the reproductive organs, testicular secretions increase metabolism and exert widespread effects throughout the body.

It is suggested that androgens, particularly those derived from the testes, contribute to the vulnerability of males, from the medical viewpoint, by this increase in the rate of metabolism, which also results in shortening the life span. In brief, Hamilton says, a price is paid for a beard and the presence of functioning testes. There may be something in this, and possibly the greater vulnerability and higher mortality among males subjected to anæsthesia and surgery are another aspect of this biological phenomenon.

In past years a certain mortality after anæsthesia and surgery was taken for granted. Nowadays, with modern methods and a steadily decreasing mortality, we search for causes in every fatal case and for explanation of variation in the incidence of these mishaps.

Clinical Science Applied to the Problems of Anæsthesia

By R. P. Harbord, M.D., F.F.A. R.C.S.

"If you consider the successive systems of Philosophy ; if you free yourself from the influence of persuasive rhetoric, intricate logic and ancient authority ; if you delve far down beneath the surface—what will you find, more often than not, but assumptions, which everyone is as free to deny as to accept ; followed by speculation and assertion, without proof ?"

These words of Lord Samuel's (1947) can be applied to our problems. Are we satisfied with the foundations of our own teaching ? Are not some of them based on assumptions ? In his Presidential Address to the Section of Experimental Medicine & Therapeutics, a little over a year ago, Professor Pickering (1949) pointed to examples of ineffective though time-honoured treatment based on assumptions.

The considerable advances made by Sir James Mackenzie in making sound the structure of cardiology show something of what can be achieved by a study at the bedside—bedside science. Sir Thomas Lewis (1935) has defined Clinical Science as : "The branch of knowledge that centres upon human beings, but which also includes directly relevant parts of allied sciences."

Hindrances to the study of man and his ills have been exposed by Wilfred Trotter (1941) who wrote :

"The observer must wait upon the natural occurrence of the phenomena he wishes to study. The phenomena may be too infrequent for their significant recurrence to come within the span of life, they may be too complex and too closely mixed with irrelevant events for the invariable sequences they possess to be detected."

Continuing in a more hopeful vein he wrote : "Science has found a means of escape from the limitation of the method of observation in the method of experiment."

Because of the spate of new drugs, all of which are potentially dangerous, and new methods, due to recent changes in the practice of anæsthesia, there is, at the present time, a real need for much careful investigation to determine what happens to patients during surgical operations.

The significance of data found during miscellaneous operations is difficult, if not impossible, to understand. Much more can be learnt by studying a group of patients undergoing the same operation, and further study of allied operations may yield additional information. By such means the results of natural experiments may be revealed.

The Making of Observations

Julian Taylor (1949) has written : "Accurate observation followed by accurate thought is a straighter route of progress and less encumbered, than the collection of figures, especially other people's, the so-called statistical method."

In making observations I have not used a special form. The essential is to record as much as possible which may be useful at some later date and which is documented so as to be intelligible. Essentials are not easy to foresee during the early stages of an investigation but, with the passage of time, the very problems that arise themselves suggest the means for their solution when possible. Impressions are of value as guiding lights : they act as a mental stimulus.

There is not enough room on what is now the standard anæsthetic record card. I refer to the special punched card system which I can only use for original data that is simple and requires no qualification. By "simple" I mean that which can be fully expressed in one or at most two or three words like "cuffed endotracheal tube", which can be encircled on a printed form, and leaves no room for doubt at a later stage. On the other hand phrases like "minor respiratory complications", "bronchitis", or "respiratory obstruction" may mean little or much or even vary in significance with different people. One would want to know precisely what was meant, or for how long the state of affairs lasted, and there is no space on the standard cards for this information.

Notes on the Observations Made in an Investigation of Anæsthesia for Rectal Operations

All the observations were personally recorded at the time of their occurrence both before, during and after the operations. The notes run into several pages for operation alone and

by the time the patient leaves hospital a small monograph has been made mainly on plain sheets with one or two columns only for repetitive type of data. In such a record there should be clearly stated all the evidence in support of a diagnosis such as "bronchitis". If records could be made on these lines by disinterested but enthusiastic observers many of the phenomena which normally appear within the single span of life could be compared.

When a few records of the kind indicated above have been made it requires a feat of memory to carry in one's head more than a fraction of the findings. The system I use is as follows :

The data are sorted on to summaries each of which has a number of coloured signals to represent important points. The summaries are specially mounted so that the signals are all visible thus conveying the predominating features at a glance as the investigation proceeds. The order of the summaries on the base mount can be readily altered which is of great value when classifying data.

The rapidity with which events occur at operation prevents one person from administering the anæsthetic and making a full record at the same time. Practically all the anæsthetics were given by the consultant anæsthetists of the Leeds United Hospitals who have co-operated fully with me.

Time has been expressed in minutes from the beginning of analgesia or anæsthesia, whichever came first. When the interval between observations exceeded 15 minutes after operation this was taken as the end of the period of continuous observation.

Blood loss at operation is an important consideration. If known quantities ($\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, 1, $1\frac{1}{4}$, $1\frac{1}{2}$ pints) of blood are spilled on to swabs and towels a good idea can be gained with a little practice of the amounts lost at operation. The estimate of blood loss obtained in this way, which I have termed the *clinical estimate*, compares well with the results gained in the same cases by an independent person, using a photo-electric method for measuring hæmoglobin on the swabs. To calculate the amount of blood one has also to know the patient's mean hæmoglobin. All the estimates were clinical in this investigation (*see* Table I).

TABLE I.—COMPARISON OF THE RESULTS OF BLOOD LOSS ESTIMATION ON SWABS AND TOWELS DURING MAJOR LIMB OPERATIONS (CUP-ARTHROPLASTY), BY A PHOTO-ELECTRIC METHOD OF MEASURING HÆMOGLOBIN, AND THE CLINICAL ESTIMATE MADE BEFOREHAND

Case reference	Blood loss estimates (in pints)	
	Clinical estimate	Photo-electric method
D.4b	$1\frac{1}{4}$	1·31
D.5a	2	1·64
D.6	$1\frac{1}{2}$	1·79
D.8	2	1·45
D.9	2	2·33
D.10	$1\frac{1}{4}$–$1\frac{1}{2}$	1·12

PREVIOUS WORK ON CASES WITH CANCER OF THE RECTUM

J. A. Lee (1947) states that there is often *considerable shock* produced in the abdomino-perineal resection of the rectum.

Frankis Evans (1947) believes that shock is largely proportional to *blood loss* in operations for cancer of the rectum. He has stressed the magnitude of the operation and also that the time factor has to be considered from the point of view of hæmorrhage.

Wilkinson (1942), referring to the perineal stage of the abdomino-perineal operation states that, "it is at this time, when the maximum effect of most spinal anæsthetic agents has been passed and the anæsthetic action is on the wane, that the patient exhibits shock most frequently".

Gabriel (1934) considers that the chief risks of the abdomino-perineal excision of the rectum are sepsis and shock. He states that: "*Shock*, most surgeons will agree, supervenes in the latter stages of the operation, particularly when the patient is turned over into the left or right lateral position, and during the final perineal excision."

Jarman (1947) states that there is a very marked fall in B.P. *when the patient is turned on to his side* for the perineal part of the operation and sometimes the B.P. cannot be recorded. Hasler (1933) states that: "For excision of the rectum spinal anæsthesia is invaluable as a means of preventing shock." Loftus Dale (1947) stated that he had abandoned spinals in favour of curare *thereby avoiding* the fall in B.P. which accompanies the *movement* of a patient from the Trendelenburg to the lateral position under spinal.

Lloyd-Davies (1947) has again stressed the magnitude of the operation and has stated that one of the most important precautions to take is the *control of the B.P.* He further stated that the *turning of the patient* during operation lowers B.P. very considerably and on occasions to dangerous levels. He therefore recommended the lithotomy-Trendelenburg position. This simultaneously exposes the abdominal and perineal fields and makes possible the synchronous combined abdomino-perineal resection, and he claims that shock is thereby minimized.

Gabriel and Wilkinson refer to shock at the perineal stage; Jarman, Loftus Dale and Lloyd-Davies refer to a fall in the B.P. on turning the patient. By "shock" do these observers mean a fall in B.P.?

Thus the following require investigation: (1) Blood loss and the duration of operation from this viewpoint; (2) change of position under anæsthesia; (3) the control of B.P.; (4) what is a dangerous level of B.P.?

I chose to watch operations on patients with cancer of the rectum because there are a number of different ways of removing the growths. I thought that a comparison might produce valuable information on the effects of surgical trauma as distinct from postural changes for there is no change of position during the perineal stage of the synchronous combined operation. These are severe operations in people in late middle or old age. I also wanted to demonstrate what is meant by "deterioration" at operation.

Observations on Cases with Cancer of the Rectum

Operative procedures.—This is a small series of 83 operations. 52 were synchronous combined abdomino-perineal resections; 19 were laparotomies without further procedure or else a palliative colostomy was carried out. One abdominal resection of the colon is included amongst this group. There were 6 perineal resections of the rectum following colostomy at a previous date, 1 abdomino-perineal resection and 5 perineo-abdominal resections.

The synchronous combined abdomino-perineal resection.—The patients were unselected. There were 33 males and 19 females. The ages ranged from 27 to 83 years, the majority being between 51 and 70 years. 7 were aged 70 years or more.

The methods of anæsthesia can be divided into two main groups: (1) intravenous barbiturate (thiopentone), *d*-tubocurarine chloride, and inhalation (nitrous oxide and oxygen; cyclopropane in only 3 cases) by the CO_2 absorption method. I shall refer to this group as the barbiturate and inhalation group, which comprised 20 cases; (2) spinal (nupercaine 1 : 200 or 1 : 1,500) with intravenous barbiturate (mainly kemithal) but without inhalation. I shall refer to this as the spinal and barbiturate without inhalation group, which comprised 21 cases.

Four cases had spinal analgesia alone; 7 had a spinal and intravenous barbiturate and inhalation.

Eight patients died; 2 within three hours of the end of operation, the remainder at intervals of from two to forty-two days after operation. It is not possible to decide what was the precise cause of death in these cases though autopsies were performed in all. In 4 peritonitis was a factor, possibly the major one; in 2 there was intestinal obstruction.

Both patients dying soon after operation had signs of circulatory collapse characterized by prolonged hypotension. Circulatory changes with hypotension were a marked feature of the clinical signs observed in most of the patients during this operation. Particular attention has been paid, therefore, to the circulatory changes in what follows.

The incidence of low blood pressure.—41 cases had hypotension of the order of 80 mm.Hg during the period of operation; 27 had hypotension in the post-operative period.

Since the anæsthetic may produce pressor effects on B.P. during its administration I have been careful to take account of the B.P. changes during the whole of the period of continuous observation which exceeds the period of operation in all but 2 cases.

The extent of the hypotension.—46 cases had systolic blood pressures of 90 mm.Hg or less. Thus practically all the cases had hypotension of this order at some time during the observations. In 9 the lowest level was between 80 and 85 mm.Hg. In 18, i.e. in over one-third, the lowest level was between 65 and 70 mm.Hg, in 5 the lowest level was 50–55 mm., in 1 it was 40 mm. and in 11 the B.P. was unrecordable.

The duration of hypotension.—Dr. Langton Hewer (1948) reports: "It has been said that a patient must not be left for more than 20 minutes with a systolic pressure below 80 mm.Hg or a diastolic pressure of less than 60 mm.Hg. If this time is appreciably exceeded death is extremely probable within 48 hours."

Hewer then adds that in his experience "patients can survive without apparent ill-effects for considerable periods with blood pressures so low that they cannot be measured".

Dr. Gillies (1948) has also noted that with total spinal anæsthesia in hypertensive patients the B.P. falls frequently to unrecordable levels, but gives no precise data relating to the duration of the hypotension. He wrote: "The clinical state described lasted an average time of 20 to 30 minutes, after which respiratory and circulatory function began to return to normal. Spontaneous pulmonary ventilation became adequate; the radial pulse again palpable, and the blood pressure although low, measurable."

Twenty-six of the patients (*see* Table V) having the synchronous combined operation had systolic pressures of 80 mm.Hg for periods of 20 minutes at least and yet 49 were alive four days after. It is therefore clear that this does not point to serious consequences in so far as life is concerned. In 30 cases the hypotension (80 mm.Hg) lasted for a period between 1–50 minutes. In this group the hypotension lasted between 1–20 minutes in 13 cases, and in 15 between 21–40 minutes.

The period during which the B.P. was unrecordable lasted only a short time. In 9 this did not exceed ten minutes. The longest period lasted 2½ hours, at the end of which time the patient died.

Blood loss at operation (*see Table II*).—15 had lost up to ½ pint (clinical estimate); 19 from 1 to 1½ pints. Only 4 lost 2 pints or over. Most of the loss came from the perineum. These losses represent external hæmorrhage and do not include extravasation of blood into the tissues.

Crook *et al.* (1946) have estimated blood loss during combined abdomino-perineal resections of the rectum in 12 cases, and found losses under 1 pint in 11 cases, of which 8 lost ½–1 pint. All had spinal anæsthesia.

Frankis Evans (1949) gives Dukes' figures as follows: "The average blood loss was between 500 and 1,000 ml. It was never less than 500 ml. and the highest figure he found to be 1,400 ml."

Normal man stands the loss of 1 pint of blood apparently without ill-effects other than an occasional fainting attack. Many normal men suffered injuries during the last war and lost as much as 2 pints of blood, and went through operation well some hours later. It does not follow that patients of the age group we are considering would tolerate relatively sudden losses of from 1 to 1½ pints under anæsthesia.

Transfusion of blood during operation (*see* Table II).—If the clinical estimates of blood loss are correct then most of the patients received blood in amounts equivalent to the losses or over (32 cases) by the end of operation. 6 patients did not have blood at all during operation though some of these had saline. Of the 20 patients whose transfusion of blood was less than the estimated loss the difference was more than 1 pint in only 5 of the cases.

TABLES II–V.—SYNCHRONOUS COMBINED OPERATION

Nos. in Body of Tables = Numbers of Cases

TABLE II.—BLOOD LOSS AND TRANSFUSION (BL & Tr)

	Clinical estimate of BL or Tr by the end of op'n (in pints)						Balance of Tr over BL by the end of operation			
	¼	¼–½	½–1	1–1½	1½–2	2	Under	Equal	Over	Not transf'd.
Transf'd. ..	4	3	17	13	5	4	20	18	14	6
BL.	6	9	9	19	5	4				

These findings suggest that low B.P. at operation is not due to loss of blood. We cannot be dogmatic because we do not know how much blood was extravasated. The next question is how much blood was lost by the time low B.P. (80 mm.Hg) was first recorded? Clinical estimates show that in the majority the loss did not exceed ¼ pint (34 cases) (*see* Table III). Since many of these patients had received some transfused blood by this time it is clear that loss of blood is not the initiating cause of the hypotension.

TABLE III.—CLINICAL ESTIMATE OF BL WHEN HYPOTENSION (80 mm.Hg) FIRST RECORDED

Pints BL.	?	Nil	VL	1/8	¼	½	⅝	1–1½	2	(VL—Hardly any)
Cases	1	18	10	1	5	4	1	2	1	

The circumstances attending the onset of low B.P. of the order of 80 *mm.Hg.*—Hypotension (of the order of 80 mm.Hg) was first recorded at three periods (*see* Table IV): (*a*) within the first 10 minutes (10 cases); (*b*) between 31 and 40 minutes (12 cases); and lastly (*c*) between 61 and 120 minutes (6 cases). Thus the periods were roughly early in operation, after half an hour and later.

TABLE IV.—ONSET OF HYPOTENSION (80 mm.Hg) AND OPERATION STAGE

Minutes:	0–10	11–20	21–30	31–40	41–50	51–60	61–90	91–120	121–150	151–180
Cases:	10	5	4	12	4	1	4	2	Onset of hypotension	
				Stages of Operation						
No. cases ..		18	28	5	1		having abdominal incision			
„ „ ..		1	30	18	2	1	„ peritoneum opened			
„ „ ..		2	18	22	8	2	„ perineum incised			
„ „ having bandages applied							16	22	9	3

These periods coincided with the steps of the operation. Most of the operations (22 cases) lasted between one and a half and two hours. 16 lasted between one and one and a half hours.

There is not a single instance of the incision of the abdomen before ten minutes. During this time the patients were given either a spinal or a general anæsthetic or both and then placed in the lithotomy-Trendelenburg position and catheterized. 5 of this group had a spinal anæsthetic and in 3 of these an intravenous barbiturate had also been given.

Hypotension occurring between 31 and 40 minutes corresponded to the time of the perineal incision in most of the cases. Immediately before the perineal incision was made the abdominal surgeon had explored the belly cavity to determine the operability or otherwise of the growth. At the time of the perineal incision the abdominal surgeon was usually stretching the attachments of the colon to the posterior abdominal wall.

Fig. 1 is a good example of a sudden fall in B.P. occurring at about this time in a patient who had lost less than ¼ pint of blood. Note how the systolic pressure was maintained at a steady level for the first 30 minutes although a spinal anæsthetic had been given. The 20 mg. methedrine which was given intramuscularly at one minute would presumably take about 15 minutes to act. It did not appear to have much effect unless it maintained the level for 30 minutes. The perineal incision was made at 28 minutes and 2 minutes later the surgeon was pulling hard on the rectum so that the patient's body shook. The colon was also being mobilized at the same time and hence it is not possible to decide which was the cause of the sudden fall in B.P. Had it been due to the spinal anæsthetic it would have begun to fall before. It might be argued that the pressor drug effect had worn off by this time so that the fall in pressure due to the spinal was delayed. As we shall see presently, however, a sudden fall at this period occurs with general anæsthesia without a spinal or a vasoconstrictor drug. Low B.P. due to nupercaine spinal anæsthesia does not occur suddenly half an hour after the intrathecal injection. I have already referred to cases with a fall in B.P. occurring within the first 10 minutes. One of these also had 20 mg. methedrine early on. Other similar results were also found with nupercaine in patients undergoing other types of rectal surgery. The clinical notes suggest the perineal manipulations were severe and it is possible that this region is the origin of an afferent depressor reflex.

The following events showed that the spinal anæsthetic was working: At 98 minutes the patient became conscious. Bandages were first applied by 109 minutes. At 128 minutes the perineal wound had to be exposed and reopened because of hæmorrhage. Hæmostasis was effected by 150 minutes. During these procedures the patient stated that he felt no pain although he was aware of the surgeon's manipulations.

Another point of interest is shown in Fig. 1. The abrupt fall in B.P. occurring at 90 minutes coincided with the change from the lithotomy-Trendelenburg to the dorsal position.

No large or moderate dose of kemithal was given at the times when the B.P. fell abruptly. The first fall occurred between 28 and 33 minutes. There were 3 doses of kemithal administered before this time, 0·6 gramme at 11 minutes; 0·3 gramme at 18 minutes and 0·2 gramme at 20 minutes. Practically no change in B.P. occurred for 8 minutes after the last dose. The second fall occurred between 88 and 93 minutes, the last dose of kemithal (0·1 gramme) being given at 76 minutes.

We can make the following deductions from this case:

(*a*) The spinal anæsthetic was effectively blocking pain sense.

(*b*) An abrupt and substantial fall in systolic B.P. occurred immediately after the perinea incision when the colon was being handled.

(*c*) The position remained constant.

(*d*) The perineal manipulations were sufficiently strong to cause jerky movements of the patient on the table.

(*e*) Neither the spinal nor the initial kemithal injections were followed by any significant lowering of systolic B.P. Subsequent doses of kemithal were less than the initial one.

(*f*) Blood loss was less than ¼ pint at the time when the B.P. had first fallen to 60 mm.Hg.

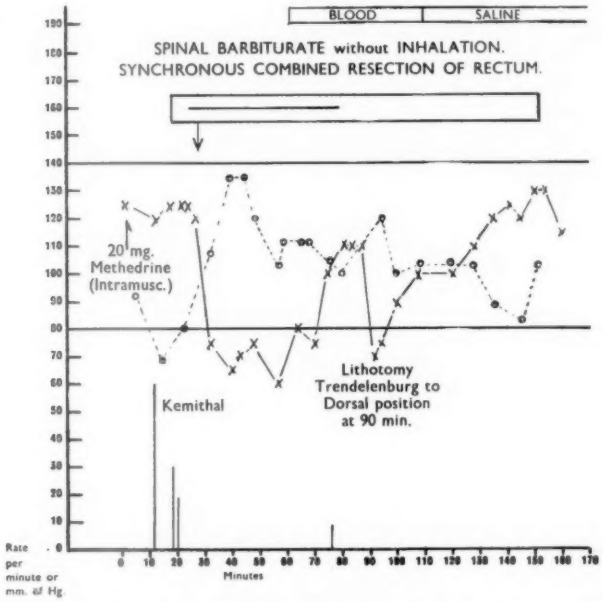

FIG. 1.—Blood loss: Very little by 47 min.; ¼ pint by 53 min.; 1 pint by 58 min. Transfusion by end of operation: Blood 1 pint; saline ¼ pint.

AN EXPLANATORY NOTE ON THE GRAPHS (FIGS. 1–5)

Crosses = Systolic B.P. Circles = Pulse rate/min.

Parallel lines at top of graph = transfusion.

Oblong = period of surgical manipulations; horizontal line within oblong = period of intraperitoneal manipulations; vertical arrow pointing downwards = perineal incision.

Vertical arrow with single barb pointing upwards = vasopressor drug.

Vertical lines at lowest part of the graphs = doses of barbiturate (10 = 0·1 gramme).

We have already stated that in a group of 12 cases hypotension of the order of 80 mm.Hg was first recorded between 31 and 40 minutes and that this period was the time when the perineal incision was made in 22 of the cases (Table IV). We shall see presently that abrupt falls in systolic pressure occurred in a significant number of cases at this stage of the operation even though it did not necessarily occur between 31 and 40 minutes.

Assuming this last statement to be correct then we can add that the evidence points to a perineal origin of a depressor reflex. In 2 cases the fall occurred after the skin incision but before the surgeon pulled on the rectum (one of these was a perineal resection of the rectum).

Overleaf is an example of a case in which the rectum is removed by the perineal approach some days after colostomy. This case has been chosen because of the clarity of the evidence and also because it shows the method of documentation.

NAME: C. C. No. B.4.

OPERATION: PERINEAL RESECTION OF THE RECTUM. Date: 27/7/48.
COLOSTOMY 10 DAYS PREVIOUSLY.

ANÆSTHESIA: SPINAL 2 c.c. 1 : 200 NUPERCAINE. NO GENERAL ANÆSTHESIA.

Mins. from zero	Time	Pulse	B.P.	Observations
−46	1540			Omnopon gr. ⅓, scopolamine gr. 1/150th subcutaneously.
− 4	1622	144	195/95	Sitting. Applying spirit to back.
− 2	24			Methedrine 30 mg. in ½ c.c. 1 : 200 nupercaine as local anæsthetic before lumbar puncture.
0	26			2 c.c. 1 : 200 nupercaine intrathecally between L. 2 and L. 3 spines.
2½	28½			Sitting position changed to dorsal.
5	31	148	205/110	
8	34			Sacral pad beneath buttocks and legs suspended in supports. Table is horizontal.
10	36		180/90	
14	40			Table wheeled into theatre and head end lowered 5 degrees.
16	42	152	190/100	Fingers warm; hand veins dilated, nose and forehead warm and dry.
18	44			Passing catheter.
21	47	152	195/90	Head end of table lowered from 10 to 15 degrees.
22	48			Towels arranged.
23	49	148	195/95	Suture of anus.
24	50			Incision of skin completely encircling the anus and growth which is plainly visible protruding externally. There are no facial grimaces and he says he does not feel any pain. Appreciates having his lips moistened.
27	53	144	185/90	The patient's head shakes with the perineal manipulations. A few oz. of blood loss now.
29	53	140	110/80	Radial pulse feels weaker but is regular. Fingers warm, forearm veins dilated. Nose and forehead warm. A very hot day. Dry skin.
32	58		80/	About 6 inches of rectum freed now. No more than ¼ pint of blood loss up to now. No transfusion.
34	1700	160	135/70	He says he is not in pain. Face colour not pale, it is slightly deeper than preop.
37	3	158	135/	No marked hæmorrhage. Now face is ? a little paler.
39	5	140	110/	Fingers, nose and forehead warm, dry skin. No change in face colour.
46	12	148	125/	No more than ¼ pint blood loss. No transfusion. Fingers warm. Has coughed about 3 times during operation. No sputum.
49	15	140	115/	Diathermy section of gut held in clamp. Face is a little paler than preop. but there is not much in it. There are only 4 fairly well-soaked dabs and there is not much more than ⅛ pint on the towels.

From this case we learn that:

(1) The spinal anæsthetic prevented the patient from feeling pain.

(2) An abrupt and substantial fall in systolic pressure coincided with perineal manipulations.

(3) The perineal manipulations were strong enough to cause slight jerky movements of the body.

(4) The systolic pressure was maintained for 27 minutes after the intrathecal injection.

(5) There were no abdominal manipulations.

(6) The position on the table was constant.

(7) Blood loss was minimal as determined by clinical estimate.

Surgical manipulations in the perineal region, which include skin and muscle incision and traction of the rectum, may produce a depressor effect on B.P. The afferent path for this reflex is not the path by which pain-producing impulses pass.

Fig. 2 shows a steady B.P. level during the first part of an abdomino-perineal resection of the rectum under general anæsthesia. The patient was then placed in the lithotomy position and the perineal part of the operation begun. An abrupt fall in systolic pressure coincided with the change of position and the perineal manipulations. No large doses of thiopentone were given at this stage, neither was there any sudden hæmorrhage. In the previous case (No. B.4) the change in position under spinal anæsthesia from dorsal to lithotomy did not

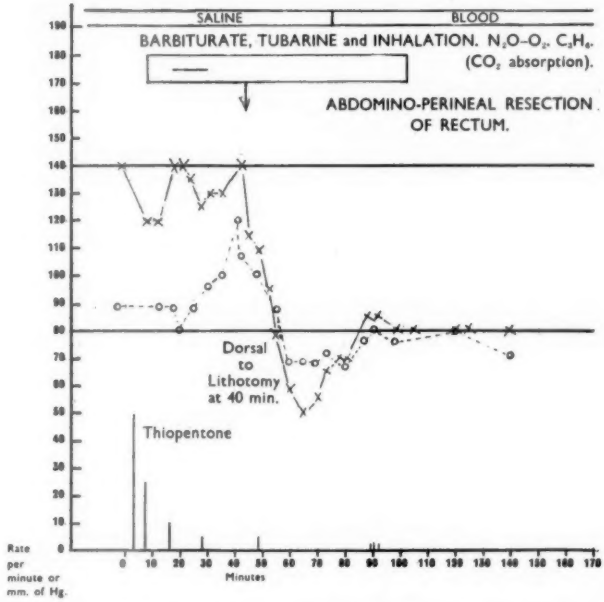

FIG. 2.—Blood loss: Very little by 49 min.; ½–1 pint by 55 min. Operative transfusion: Saline ½ pint; blood ½ pint.

produce a fall in B.P., whereas in Fig. 1 towards the end of operation a fall was associated with the change from the lithotomy-Trendelenburg to the dorsal position, there being no alteration with the initial position of the patient. I need further evidence on these points but at present suspect that the change from the dorsal to the lithotomy position is not associated with a fall in B.P. It has actually been advocated by Hingson and Southworth (1946) that a similar position to the lithotomy be used to treat cases with low B.P.

Although pressor factors at operation predominated in one group of cases, nevertheless some depressor response could be seen soon after the perineal incision. That the pressor factor was in some cases due to the anæsthetic was shown by the marked fall in B.P. on removing the mask of inhalation apparatus.

There were also examples showing a marked depressor effect coming on within the first ten minutes of the induction of analgesia. During this period the intrathecal injection of nupercaine, with or without an intravenous injection of barbiturate, had been made but the surgeon had not incised the skin. In some cases the fall occurred in spite of the previous use of vasoconstrictor drugs. When the perineum was incised later there was no change in B.P.

The abrupt fall in B.P. after the perineal manipulations have begun suggests, in the case of spinal anæsthesia, that the analgesic solution may not completely block the spinal pathways. It may be that only the nerve roots entering the spinal cord which are bathed in solution are blocked while the nerve fibres deep within the cord are free to transmit impulses. Thus if the roots in the lumbo-sacral region were not brought in contact with the anæsthetic, then impulses might enter here and pass up within the cord beyond that part which is in contact with the analgesic solution. One can readily imagine this happening with the Etherington Wilson technique.

Of the 32 synchronous combined abdomino-perineal operations performed with spinal anæsthesia, either alone or combined with general anæsthesia, no less than 12 had a steady level or a rise in B.P. before the perineal incision followed by a fall after it. This type of depressor response (not necessarily amounting to hypotension) was recorded in 1 out of 6 cases having spinal anæsthesia with 1 in 1,500 nupercaine by the Etherington Wilson technique; in 4 out of 6 with the Howard Jones technique and in 4 out of 6 with heavy nupercaine.

Early in the investigation I discussed the depressor responses occurring at the perineal stage of the operation with my colleagues in Leeds. As a result we decided to use what we then thought was a new technique. It consisted in giving heavy nupercaine to a patient in the sitting position and after 2 minutes injecting light nupercaine, keeping the patient sitting and continuing as in the Etherington Wilson technique. This method which we call the "combined" technique has been described before by Wilkinson (1942) who stated that it was first suggested to him by Nosworthy. We have been surprised to find a depressor response at the time of the perineal manipulations in cases conducted with spinal anæsthesia by Wilkinson's combined technique. It has been recorded in 3 out of 14 cases.

Further experiments have been tried. In 4 cases the perineum has been injected with procaine. One of these had a depressor response. In 4 the presacral region has been infiltrated with procaine. 3 of these cases had a depressor response at the time of the perineal manipulations. These experiments, which do no harm to the patient since they are normal procedures, involve small numbers of cases but are mentioned because I hope that others may be induced to use them to better advantage than I have been able to with the material in Leeds. They would be most usefully employed in the perineal resections of the rectum rather than with the synchronous combined operation, since we cannot be sure that the depressor responses occurring at the time of perineal trauma are not due to the abdominal manipulations.

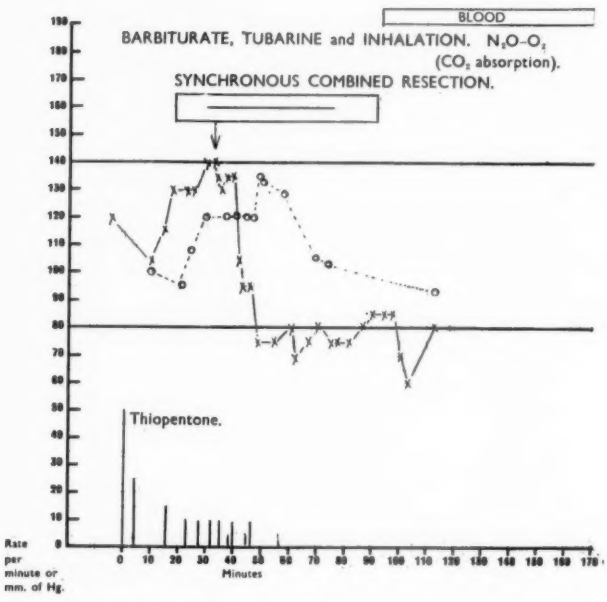

FIG. 3.—Blood loss: Very little by 27 min.; ½ pint by 42 min.; 1 pint by 59 min.; 1½ pints by 75 min. Transfusion: Nil during period of surgical manipulations.

Earlier, I mentioned an example of the depressor response occurring with general anæsthesia without spinal anæsthesia (*see* Fig. 3). In a group of 20 cases a depressor effect on B.P. was recorded in 11 cases beginning at the time of the perineal incision. I happen to have

a small series of upper abdominal operations conducted with the same method of anæsthesia. Out of 13 operations there was only one with hypotension. I rather suspect that pulling on the colon does not regularly produce hypotension.

The evidence which we have produced is that an abrupt fall in systolic B.P., during the synchronous combined operation, is related by time to the period when the perineal part of the operation is begun. This change has also been demonstrated in the perineal resection and also in the abdomino-perineal operation. Neither general nor spinal anæsthesia by various techniques, including the combined method, prevents the abrupt depressor change.

Another possibility is that the impulses which result from surgical trauma pass along nerves with relatively thick myelin sheaths. It is known that in the lumbar region there are many such fibres and that pain producing impulses pass along those with thin myelin sheaths.

It may be that the traumatic impulses pass to the spinal cord via the sympathetic or other nervous systems above the area which has been blocked by the spinal anæsthetic. Some of the sympathetic pathways pass into the upper thoracic segments of the cord. Hence the experiments with local infiltration in the presacral area.

Rovenstine *et al.* (1942) state that: "B.P. may change very little during high spinal anæsthesia in normal, unoperated man". Their interpretation of the significance of it is different from the one I have indicated above. They added: "The extreme falls observed in operated subjects are believed to be the result of decreased venous pressure (and hence decreased cardiac output) following opening the abdomen and the attendant operative procedures, inflicted in the face of vasomotor paralysis and loss of vasomotor defence."

We have already stated that there was a group of 7 cases developing hypotension of the order of 80 mm.Hg towards the end of operation. Besides these 21 showed a depressor response at the end of operation. In 6 cases this was considerable in extent (i.e. more than 70 mm.Hg). Scrutiny of the records shows that there were three circumstances occurring at this time: (1) the disconnexion of anæsthetic apparatus; (2) the reduction of the head-down table tilt; (3) the change from the lithotomy-Trendelenburg to the dorsal position. It was not possible in these cases to determine which was the major depressing factor as all three often occurred at about the same time. Fig. 4 shows a typical example.

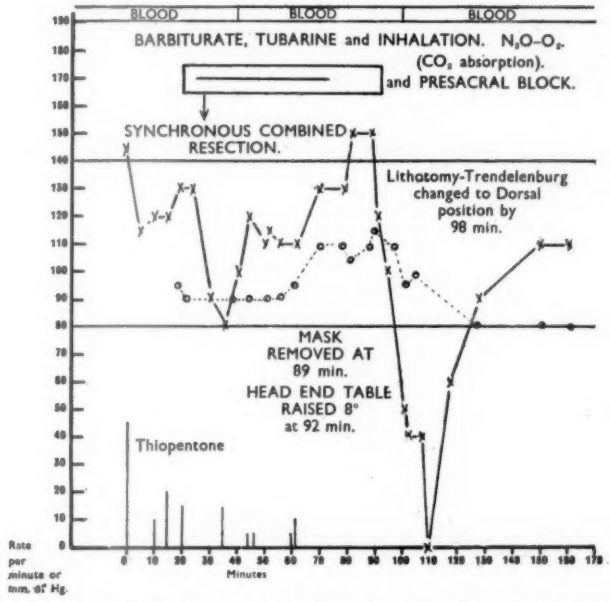

FIG. 4.—Blood loss: Very little by 27 min.; ¼ pint by 33 min.; ¾ pint by 53 min.; 1 pint by 71 min.; 1½ pints by 94 min. Transfusion: ½ pint blood pre-operatively, 1½ pints at operation.

Thus there are three periods of potential danger to the patient during the synchronous combined operation which are either at the beginning of anæsthesia, at the time of the perineal manipulations or at the end of operation. At such times deterioration shown by lowered B.P. may occur.

Attempts to control the blood pressure.—Vasopressor drugs were used in 26 cases, 19 had pholedrine, 4 ephedrine, 2 methedrine and 1 had icoral. In 5 the pressor drugs were given before operation but the remainder of these drugs were administered during operation.

Individual cases having pholedrine showed a rise of B.P. in practically all cases, the greatest being 115 mm.Hg. Hypertension resulted in 7 cases but was transitory. The pressor response was abrupt. In No. A.48 there was a rise of 65 mm.Hg in three minutes; in No. A.47 it was 75 mm.Hg in 6 minutes. The B.P. rise was not maintained as is well illustrated in Fig. 5.

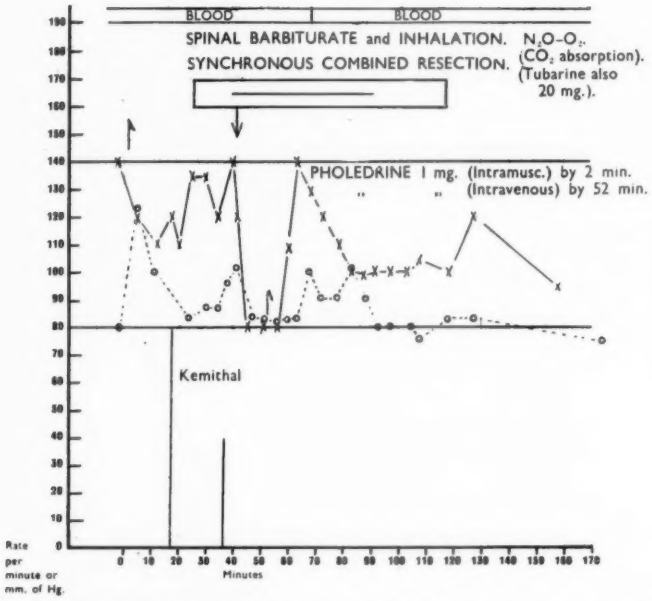

FIG. 5.—Blood loss: Very little by 44 min.; ¼ pint by 47 min.; ¾ pint by 101 min. Transfusion: ½ pint blood pre-operatively, ¾ pint at operation.

The whole effect appeared to be over in from 20 to 30 minutes after intravenous injection. The tendency of the B.P. curve appeared to be generally unaltered after the effects of the drugs had worn off.

After the intravenous injection of pholedrine it was possible to detect by ordinary palpation a narrowing of the radial pulse. This is direct evidence of peripheral arterial vasoconstriction. The superficial veins appeared to be the same width as before.

Vasoconstrictor drugs were used in only 2 of the cases with anæsthesia by inhalation and in 13 of the 21 with spinal and intravenous anæsthesia without inhalation. In both groups the incidence of hypotension of 80 mm.Hg maintained for 20 minutes was roughly the same. This suggests that these drugs were generally ineffective. In my opinion the best time to use them is at the end of operation if the B.P. falls as a result of the circumstances occurring at this time, which I have enumerated above. I have only used the continuous adrenaline drip (1 : 250,000) on one occasion in a patient with hypotension due to peritonitis some days after operation. Speeding the drip cautiously failed to have the desired effect. I am against the routine use of this method because its effects may conceal the true state of the patient, and it may constitute an unnecessary burden to the patient.

Comparisons of anæsthetic combinations.—Table V compares the effects of the main anæsthetic combinations. From these we note the following points some of which have been mentioned before:

(1) 5 cases having spinal and intravenous anæsthesia had losses of blood of the order of ¼ pint or less. None of the inhalation group had losses as small as this. The losses were on the whole greater in the inhalation group.

(2) Most of the cases were fairly well transfused by the end of operation. In many cases more transfusion was given after the end of operation.

(3) Vasopressor drugs were used mainly in the spinal group.

(4) Low B.P. of the order of 80 mm.Hg lasting for 20 minutes or more during the period of continuous observation occurred frequently and in approximately the same numbers in the two main groups.

(5) Rapid pulse-rates of the order of 120 beats per minute were found in about the same number in both main groups.

(6) Facial pallor was noted at operation in 15 of the main spinal group and in 7 in the inhalation group.

(NOTE.—Hypotension applies to the period of continuous observation. Other signs related to the period of operation. Fast pulse = 120 per minute, or more.)

It would appear that the inhalation group were in better shape at operation than the spinal and intravenous group if general condition went hand in hand with facial colour. The depth of facial colour soon decreased after the inhalation, and in some cases a marked fall in B.P. was recorded after the mask was removed. The amount of blood lost was more in the inhalation group. The 2 cases ending fatally within three hours of operation both had inhalation anæsthesia.

The patients with spinal and intravenous anæsthesia without inhalation looked paler at operation but this does not mean that they were in poorer condition; one of them vomited during operation. This is a distinct disadvantage but the anæsthesia produced by the barbiturates was no more than a sleep. It was not deep anæsthesia. On the whole I personally favour this method though I should prefer to give a stream of oxygen continuously via a small nasal catheter.

Findings During other Allied Surgical Procedures

The findings in cases belonging to the alternative operative procedures and in inoperable cases were as follows (*see* Tables VI and VII):

(1) Low B.P. and rapid pulse-rates were present in most of the small group of cases comprising abdomino-perineal, perineal resections and perineo-abdominal resections (Table VI).

(2) The last group (Table VII) shows the inoperable cases in whom nothing was done after the growth had been found to be too extensive for removal or in whom the liver was the seat of secondary growths. In a few of these a palliative colostomy was carried out. This group also includes one abdominal resection of the colon. Blood loss and transfusion was minimal in these cases. Hypotension of the 80 mm.Hg order lasting for twenty minutes or more was present in only 5 of the 20 cases.

Thus hypotension (80 mm.Hg for 20 minutes) occurred in ¼ of the cases having laparotomy and in ½ those with the synchronous combined operation. Blood loss was minimal in the former and was made up by transfusion in the latter group. Anæsthesia was roughly comparable; the main difference being in the amount of surgical manipulations. This may be the factor responsible for the difference in the extent of the hypotension, although as we have seen, hypotension was produced in the initial stages in some cases.

The Post-operative State (Synchronous Combined Operation)

I have indicated that the immediate post-operative period is a good time to assess the condition of the patient. I have classified the clinical signs in Tables VIII and IX.

Table VIII shows the states encountered in patients who did not have hypotension of the order of 80 mm.Hg in the post-operative period. The main point of importance is that practically all cases have a period when there are signs of vasoconstriction. Note also that the cooling of the extremities is not reflected by the temperature of the forehead. Changes in temperature were roughly assessed by the observers' warm hands.

C—constricted. N—normal.

Table IX shows the signs in those who had hypotension of the order of 80 mm.Hg in the post-operative period. I was unable to record the level of B.P. in 6 cases at varying times after operation. 2 of these died in the hypotensive state. In 12 cases B.P.s of 50 mm.Hg were recorded.

Pulse-rates of 120/minute or more were not frequent, only 7 cases having rates as fast as this in the whole series. Many cases in both groups had relatively normal pulse-rates.

The point to note about these two Tables is that vasoconstriction was a state common to both groups and that the distinguishing feature was the level of systolic blood pressure. The state of vasoconstriction does not *per se* mean that the patient is ill.

Since periods with systolic pressures in the region of 80 mm.Hg occur in roughly half the cases this state, even with vasoconstriction, does not indicate that serious consequences will follow from a circulatory point of view. The 2 patients who died soon after operation had either pressures about the 40 mm.Hg level or the pressures were so low as to be unrecordable. These low pressures were accompanied by fast pulse rates. Pulse-rates varied in those who recovered with low B.P., but they were mainly below 100/min.

These findings indicate that systolic levels about 50 mm.Hg are to be regarded as definite signs of circulatory danger during the post-operative period.

Degree of hypotension and post-operative state in patients after the synchronous combined operation. (Only includes those with pressures of 80 mm. or less.) D – died soon after operation.

The R.R.H. CO_2 Indicator

I have previously referred to pressor changes at operation which may be due to the inhalation of an excessive amount of CO_2 gas in rebreathed mixtures.

Dr. S. T. Rowling, Mr. Ringrose and myself (1950) have together produced an instrument which is capable of measuring CO_2 reasonably accurately in the presence of other anæsthetic gases. It can be used continuously during the administration of anæsthesia and is being used by us now to investigate the pressor changes due to anæsthesia. A detailed account of the instrument will be found in the *British Journal of Anæsthesia*.

Summary

The need for the application of Clinical Science to anæsthetic problems has been stressed. The disadvantages of the present system of recording in anæsthesia have been exposed and an example of a more adequate documentation illustrated. The material offered by clinical hospital practice did not lend itself to research as in the laboratory, yet the *method of observation*, as illustrated in this paper, was confined to specific groups of operations in man and, further, comparisons of the effects observed enabled what was tantamount to the *method of experimentation*, without subjecting the patient to any unnecessary procedure.

Hypotension was a characteristic feature of the *synchronous combined* abdomino-perineal resection operation and, in spite of this, the majority of patients recovered. 2 of the 52 cases died soon after operation with prolonged hypotension (40 mm.Hg and unrecordable). The observations indicated that external blood loss is not the cause of hypotension.

Three periods of deterioration as shown by a fall in B.P. occurred either initially—between 31 and 40 minutes from the beginning—and at about the end of operation. The factor operating initially was mainly the anæsthetic; between 31 and 40 minutes, the perineal and abdominal manipulations; at the end of operation the three factors were: (*a*) levelling of the table, (*b*) change from the lithotomy-Trendelenburg to the dorsal position, and (*c*) release of anæsthetic pressor influences.

Records made of the clinical signs in the *perineal* and the *abdomino-perineal* resections of the rectal operations, pointed to a depressor effect on B.P. at the perineal stage irrespective of changes in position.

Modifications in the technique of spinal anæsthesia failed to prevent depressor effects on B.P. at the perineal stage of the *synchronous combined* abdomino-perineal operation.

Surgical manipulations in the perineum (without abdominal manipulations) under spinal analgesia alone, resulted in a fall in B.P. although no pain was experienced by the patient.

The use of vasopressor drugs (mainly pholedrine) did not materially alter the general B.P. curve at operation. A comparison of anæsthetic combinations with the *synchronous combined* operation indicated that blood loss was less in the group having spinal and I.V. barbiturate without inhalation, compared with the group having I.V. and inhalation anæsthesia, with a muscle relaxant drug. Facial pallor occurred in twice as many cases in the spinal as in the inhalation group.

A study of the post-operative stage shows that vasoconstriction, particularly of the face and limbs, was common to most of the cases and indicates that the critical level of B.P. is about 45–50 mm. of Hg.

My thanks are due to all those who have assisted me in this work and, in particular, to the anæsthetists and surgeons of the Leeds United Hospital.

Section of Dermatology

President—W. N. GOLDSMITH, M.D., F.R.C.P.

[*December* 15, 1949]

Case for Diagnosis. ? Dermatitis Nodularis Necrotica.—R. E. CHURCH, M.B., for C. H. WHITTLE, F.R.C.P.

D. B., male, aged 33. Two years' history of an itching eruption on the trunk, limbs, neck and face; the lesions commence as papules, become pustular and ultimately ulcerate leaving scars. Hæmorrhagic lesions have been noticed on the hands. Relapses occur in crops with mild fever; the last severe crop was four months ago. A few active lesions are always present.

Admitted one year ago to Addenbrooke's Hospital, Cambridge, after a hæmatemesis of 2 pints, subsequently shown by barium meal to have been caused by a subacute duodenal ulcer. A test meal, however, showed complete achlorhydria. Ulceration of the palate and fauces was then present which has left similar scars to those on the skin.

In 1943 he had malaria and dysentery while in Egypt.

On examination.—The patient is puny and sallow-complexioned. Multiple varioliform scars, some pale, others pigmented, are present over the face, lips, palate, neck, limbs and trunk.

Active lesions in all stages, from red papules and papulo-pustules to indurated nodules with an ulcerated centre, are present over the dorsæ of hands, the arms and trunk (Fig. 1). The ulcers are circinate, deep and about 1 cm. in diameter, forming ultimately a dry scab, then healing (Fig. 2).

FIG. 1.—Distribution of eruption.

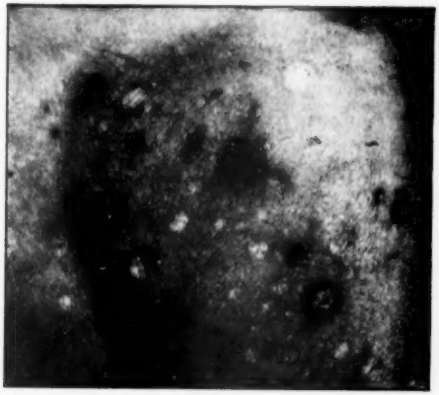

FIG. 2.—Showing necrosis and scars over shoulder.

(Photographs by Mr. K. Titterington.)

There is a generalized lymphadenopathy consisting of firm, discrete, painless glands. The liver and spleen are impalpable.

No abnormality detected in other systems.

Investigations.—Mantoux test negative (including 1 : 10). X-ray chest, lungs clear. W.R. and Kahn negative. Blood count, an eosinophilia of 21% of 8,100 white cells.

Sternal puncture normal, save for slight eosinophilia.

Sedimentation rate (Westergren) 26 mm. (= 12 mm. corrected) per hour.

Biopsy of an early papule shows a wedge-shaped area of necrosis involving the epidermis and superficial corium surrounded by a cellular infiltrate which tends to be perivascular and consists of histiocytes and lymphocytes with very few other cells. The vessels in the papillary layer are dilated, with a surrounding cellular infiltrate throughout the length of the section.

Biopsy of a cervical lymph gland shows only inflammatory change with much hæmosiderin present.

Comment.—The nature and course of the lesions together with the absence of signs of tuberculous infection suggest the diagnosis of dermatitis nodularis necrotica, in which disease the hypothesis of a tuberculous ætiology has been discarded (Sutton and Sutton, 1949). Three recorded cases of this disease have had similar necrotic ulcers in the mouth (Duemling, 1936; Cannon, 1930; Niemann and Wise, 1939).

The histological structure, which shows inflammatory change in and about the blood vessels with a secondary necrosis, has suggested an embolic process (Duemling, 1930; Jablonska, 1949), but in most reported cases attempts to isolate the causative organism or find a focus of sepsis failed.

In this patient the white blood cell count shows a marked and constant eosinophilia which may indicate an allergic rather than an infective process.

POSTSCRIPT (12.5.50).—The patient has recently developed an acute gangrene of the right index finger. There is now an eosinophilia of 32% of a total W.B.C. count of 17,000, many of the eosinophils being vacuolated—(Dr. Martin Hynes).

Although no further confirmation can be obtained, it seems possible that this may prove to be a case of periarteritis nodosa.—R. E. C.

Dr. H. Haber: I have seen a case in a woman of 30 who for the last fifteen years has been suffering from ulcers of the mouth and vulva. She also had acneiform pustules of the face. The ulcers in the mouth were of the aphthous type and left deep scars. The ulcers on the vulva closely simulated those seen in Dr. Whittle's case. They, too, left scars. Biopsy performed on an ulcer of the vulva disclosed a peculiar histological picture similar to that seen in reticulosis. There were no changes indicating periarteritis nodosa. I feel that we are dealing here with a virus infection.

? Reticulosarcoma. ? Eosinophilic Granuloma.—C. H. WHITTLE, F.R.C.P., A. LYELL, M.B., and R. E. CHURCH, M.B. (Shown by permission of Professor J. S. MITCHELL and Dr. M. BENNETT).

K. R., a farmer, aged 45.

Presenting symptoms were enlarged lymph nodes at back of neck noticed two years ago. Others appeared in epitrochlear and inguinal groups. There was also a rash in the groin. The left upper eyelid showed infiltration one year ago and in the last three months there appeared the swellings now present on the face, and his general condition has deteriorated.

He also has considerable œdema of feet and legs, and subcutaneous lumps on the dorsa of hands. ? "ganglia". On the trunk and legs there is some marmorate erythema, but no tumours are present. The liver and spleen are grossly enlarged and so are axillary, epitrochlear and inguinal lymph nodes. There has been no generalized pruritus.

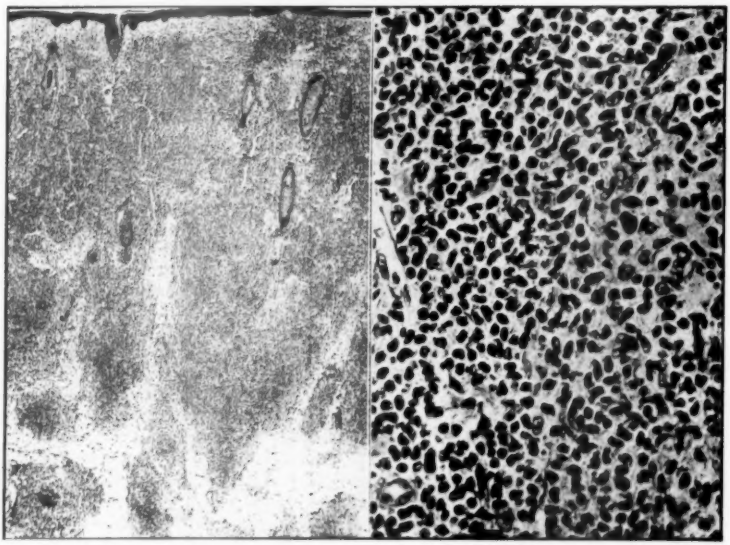

FIG. 1. FIG. 2.

FIG. 1.—Low power. Showing the thickness of skin and subcutaneous tissue involved.

FIG. 2.—High power. Showing primitive cells with abundant cytoplasm and reticulum fibres. (Photographs by S. W. Patman.)

The facial lesions, which are reminiscent of leukæmia, are striking and consist of bluish-red induration and infiltration of the skin and subcutaneous tissues, with gross enlargement of the forehead, nose and cheeks and upper eyelids. There has been constant eosinophilia in the blood, which has varied from 40–45% (5,000 to 11,000 per c.mm.).

W. and Kahn negative. Nasal swabs: Hansen's bacillus negative.

Blood count (9.12.49, Dr. J. Marx).—Red cells 4,230,000; Hb 11·4 mg. per 100 ml.; Leucos. 12,000 (neutros. 40·5, eosinos. 45, basos. 0·5, lymphos. 11, monos. 3% per c.mm.)

Sternal marrow count.—Eosinophilia only; no other abnormality. Eosinophil myelos. 5·8%, eosinos. 11·6% (Dr. F. W. Gunz).

Chest X-ray: Enlarged right hilar gland. Effusion right base (Dr. ff Roberts).

X-ray of long bones revealed no abnormality.

Biopsy of first and second lymph glands (cervical) (28.7.48 and 27.4.49).—Eosinophils present in the connective tissue outside, very few in the pulp. Probably reticulosis; no evidence of Hodgkin's disease. *Biopsy of third lymph gland* (2.12.49).—Vascular changes are the most striking feature. The arterioles of many of the follicles are converted into whorls of fibroblast-like cells, and in many of the (larger) arterioles in the capsule of the node there is intimal thickening, often with reduplication or interruption of the internal elastic lamina. One arteriole has fibrin and red cells in a segment of its wall. There is no cellular infiltration in or around the affected vessels. *Biopsy of eyelid* (28.7.48).—Much cellular infiltration; the predominant cells appear to be lymphocytes, but there are abundant eosinophil leucocytes and apparently frequent plasma cells; not suggestive of Hodgkin's disease; probably a reticulosis (Dr. A. M. Barrett).

Skin biopsy (taken 7.12.49: report received 15.12.49).—There is massive cellular infiltration deep in the corium, but reaching right up to the epidermis (*see* Fig. 1). The cells vary

considerably in appearance, but are not divisible into distinct types. The smaller cells resemble large lymphocytes but there are also frequently larger cells which do not correspond with any normal forms (*see* Fig. 2). It is amongst these that mitoses are fairly frequent. There is an abundance of reticulum fibres probably intimately related to the cells. There are occasional eosinophils but these constitute only a very small proportion of the free cells. There are small foci of fibrinoid degeneration. Vascular changes present are similar to those described in the lymph node.

The picture does not suggest Hodgkin's disease or mycosis fungoides, and on the whole fits in more with reticulosis or reticulo-sarcoma, with the balance slightly in favour of the latter: on the other hand the vascular changes and the blood eosinophilia suggest an allergic state (Dr. A. M. Barrett).

Dr. Whittle: The skin biopsy report, received only to-day, showed that this condition, in spite of the persistent high blood eosinophilia, is not in fact an eosinophilic granuloma. Moreover the process, whatever it be, is affecting other organs besides the skin. Weidman (1947) and Lewis and Cormia (1947) have thrown doubt on the existence of the eosinophilic granulomas of the skin.

Four days ago the patient had X-ray treatment to his right forehead, and I think the lesion on the right forehead is smaller than on the left, and that it is responding. If this patient is to be irradiated, he must be irradiated all over; it may be, however, that nitrogen mustard may prove a more effective therapeutic measure.

I recall a remark by the President on the reticuloses (1944): "We clinicians must not throw up the sponge and just let it drop anywhere in the reticular basket; it will remain our job to differentiate, for that is the meaning of diagnosis."

POSTSCRIPT.—1.2.50: The lesions on the face have almost disappeared following the X-ray treatment, but X-ray treatment to the trunk has not been followed by lessening of œdema in arms and legs.

28.2.50: After X-ray treatment—500 r to face, neck, axillæ and groins—the lesions have practically disappeared leaving only patches of erythema on the face. The œdema of the arms and legs has almost disappeared and his general condition has gradually improved. The tumours appear therefore to be highly radio-sensitive (C. H. W.).

20.5.50: The response to irradiation was unusual in that it was slow, but up to date the condition has cleared completely, and has shown no tendency to recur, and the patient is up and about (Dr. M. Bennett).

Eosinophilic Granuloma of the Skin.—A. J. ROOK, M.B.

A married woman, aged 68. In April 1949 she noticed a small brown spot on the nose, which has slowly enlarged.

She is the mother of 3 healthy children now aged 34, 33 and 28, and until 1945 had never been seriously ill. In January 1946 she was referred to a Chest Clinic on account of a cough which had become worse over a period of three to four months. Dr. J. H. Dadds reports: "When she was first seen at the clinic her chest X-ray showed exudative infiltration in the right upper lobe. Sputum was positive for tubercle bacilli on more than one occasion. She made very good progress with prolonged bed-rest followed by sanatorium course, with fibrosis and healing of the lesions which have been regarded as quiescent since early in 1947." Her general health is now excellent.

Examination.—On the right side of the nose is an infiltrated slightly raised, sharply defined plaque about 1 cm. in diameter, brownish-red in colour and rubbery in consistency.

General physical examination reveals no abnormality other than diminished air entry and some dullness to percussion in the right upper chest.

Blood count (20.11.49).—Total white cells 6,300 (polys. 39, eosinos. 3, lymphos. 55, monos. 3%).

Blood Wassermann ++, Kahn, strong positive.

Biopsy.—The very small specimen obtained shows the dermis to be heavily infiltrated by lymphocytes, plasma cells and a large number of eosinophils.

Comment.—The resemblance of this case both clinically and histologically to those shown to this Section by Wigley (1945) and Borrie (1949) is remarkably close. The literature on eosinophilic

granuloma of the skin is very confused, as the term has not been restricted to any single clinical or pathological entity. Lever, *et al.* (1948) pointed out that among the heterogeneous collection of cases recorded under this diagnosis, there is a group of cases showing a number of features in common. The patients are characteristically middle-aged men or women, who develop on the face from one to five purplish or reddish-brown infiltrated plaques from 1 to 10 cm. in diameter. The lesions persist indefinitely and are not permanently influenced by fractional X-ray therapy. There is no evidence of involvement of any other system. Histologically the lesions show a mixed dermal infiltrate in which eosinophils are present in large numbers.

This case and Wigley's and Borrie's cases are all apparently identical with those collected by Lever. The positive blood W.R. is interesting, and the patient will be given specific treatment, but it seems improbable that the skin lesion is related to the syphilitic infection.

Dr. H. J. Wallace: These cases seem to afford a good example of the differentiation Dr. Rook mentioned between this so-called eosinophilic granuloma with a characteristic clinical and histological appearance, and other granulomata of varying appearance both clinically and histologically, with eosinophilia as an incidental finding. The characteristic appearance of the first type seems to be a localized infiltration of the skin with this curious bronze colouring. Dr. Whittle has mentioned the number of reticulocytes and eosinophils which are to be seen in his case, but there is no reason to suppose that this is related to the eosinophilic granuloma shown by Dr. Rook. For example, some patients who show the clinical course of mycosis fungoides may have lesions apparently granulomatous in character with a predominance of eosinophilic cells.

? Lichen Nitidus.—A. D. PORTER, M.D.

Woman, aged 60.

History of nasal catarrh, pneumonia and pleurisy (no fluid).

An eruption on the trunk was first noticed two years ago and since then has spread slowly to limbs, neck and face.

Examination showed numerous discrete papules 1–3 mm. in width, scattered over the trunk and limbs, with many pigmented macules. The papules are pink, yellowish, or flesh-coloured, and some are flat-topped and lichenoid, while others are dome-shaped and covered with a scale attached at its periphery and free in the centre. Some of the papules resemble "apple jelly" when seen through a glass slide under pressure and suggest a tuberculide. Fading papules tend to be replaced by a pigmented macule.

Biopsy showed a typical tuberculous structure. No acid-fast bacilli were seen and guinea-pig inoculation was negative.

Skiagrams.—Chest, thickened pleura at the right base; sinuses, thickened lining of the right antrum; bones of the hand showed no abnormality.

Mantoux, 1:10,000, was negative on two occasions.

Blood showed a mild secondary anæmia.

Sarcoidosis may be excluded.

It occurred to me that the case rather resembled one shown by Dr. Wallace about a year ago as lichen nitidus.

Dr. H. Haber: The histology revealed a tuberculoid granuloma arranged round blood vessels and situated within the upper third of the corium. It resembled lupus vulgaris or tuberculoid leprosy. There was a rather increased lymphocytic infiltration round foci of endothelial cells, pointing against a diagnosis of sarcoid. I think this case belongs to the group of papular tuberculide.

Erythema Induratum (Whitfield).—F. RAY BETTLEY, F.R.C.P.

D. C., unmarried, aged 50. Manageress. Occupation involves standing all day.

History.—Ovarian cyst removed thirty years ago. Rheumatism in knees and elbows. Has had varicose veins for twelve years. Had a right Trendelenburg operation in 1948.

Family history.—Two brothers died of pulmonary tuberculosis. One sister died of cancer. One brother and two sisters alive and well.

Present illness.—For ten years tender red nodules have appeared on the calves, anterior surfaces of thighs, on the buttocks, arms and forearms. In size they are up to 1 in. in diameter. Their colour gradually changes to purple and after some months they disappear, leaving a pigmented stain. None of the lesions has ever ulcerated or discharged. There appears to be no clear seasonal variation.

On examination.—Several slightly tender nodules are to be felt, varying in size from ¼ to ½ in. in diameter. Many of them have left a residual brownish pigmentation. The lesions are chiefly to be found on the calves, with isolated ones on the other parts mentioned. A few inches above the ankle several lesions have run together to form a purple indurated area 2 or 3 in. across. The legs feel rather cold, but vascular pulsation is within normal limits.

General examination revealed no abnormality. B.P. 140/90.

Blood.—W.R. negative; normal blood count; blood urea normal; serum protein 7–8 grammes %; A/G ratio 1·2/1.

Skiagrams of chest, hands and feet, soft tissues of legs were all normal. Mantoux 1 : 1,000 negative, 1 : 100 strongly positive.

Biopsy (lesion about 2 weeks old, from the leg).—Histological section shows the main changes to be situated in the hypoderm. The epidermis shows a little hyperkeratosis, and in the dermis there is some perivascular round-cell infiltration.

In the fatty tissue of the hypoderm is a necrotic area, and much of the surrounding tissue shows cellular infiltration. This dense infiltration contains, in places, a fair number of polynuclear cells, but is, for the most part, made up of histiocytes and fibrocytes. One or two giant cells of the foreign body type can be found, but they are not a prominent feature. Two surprisingly thick vessels are present in the section. They are not degenerated, inflamed or thrombosed and appear to show either simple hypertrophy, or are rather large arterioles strongly contracted down. Serial sections do not show vascular thrombosis.

Comment.—This non-tuberculous form of erythema nodosum appears to have been first identified by Whitfield (1901) and subsequently mentioned by him in 1905 and 1909. He points out that erythema induratum in women under the age of 25 is nearly always tuberculous, and that over 30 it is nearly always not.

A case of apparently similar sort was shown here by Forman in 1938 under the name of lipophagous granuloma, a name coined, I believe, by Telford (1937) to describe lesions of this kind. Included under this heading are the similar lesions on the legs seen in old poliomyelitis patients. In the discussion at that time Sir Archibald Gray said that Dr. Forman's case was in the same class as Whitfield's erythema induratum.

The present case appears to fit in closely with Whitfield's description and also with the condition described by recent American authors as nodular vasculitis.

Montgomery *et al.* (1945) mention all the features of to-day's case and finally they say that they do not know what the condition is. It seems a pity to resurrect this morbid entity under a new name and to discard the name of Whitfield who originally described it.

Although there are conspicuous vascular changes they appear to me to be hypertrophic or obliterative rather than inflammatory. For this reason the term vasculitis may not be a happy one, but it seems that Telford was right in saying that the changes in the fatty tissue are vascular in origin.

Dr. Arthur Rook: In France cases of this type and Bazin's disease are grouped together under the convenient but purely morphological designation of "dermohypodermites nodulaires" and are considered to be "allergides". Whereas Bazin's disease is accepted as being of tuberculous origin, these other cases are regarded as a similar type of reaction to the streptococcus and are said sometimes to respond to treatment with sulphonamides.

Dr. P. J. Feeny: I have had one example of this condition in which the patient also had scrofuloderma in an abdominal scar and phlyctenular conjunctivitis.

Mycosis Fungoides.—P. HUGHES, M.R.C.P. (Introduced by J. E. M. WIGLEY, F.R.C.P.).

Past history.—W. T. B., aged 68. A Commercial Traveller in paraffin oil. Enjoyed good health from the age of 15 until six years ago.

At the age of 15 shortly after commencing handling paraffin oil he suffered from a red scaly type of rash, which apparently cleared up in a few weeks.

He was very worried in 1944 following loss of shop by fire, and received medical attention for some weeks because of insomnia, nervousness, &c.

Family history.—One sister had eczema when infant. Nothing else of importance.

Present illness.—June 1948 first noticed red, scaly patches on front of legs, extending from just below the knees to one inch above ankles. Severe itching in these areas prevented

the patient from concentrating on his work. Troubled by lack of sleep on account of persistent pruritus. He sought advice after a month from Medical Practitioner.

June 1948–January 1949 he was treated by sedatives, and local application of calamine lotion.

The eruption had gradually spread to trunk, limbs, scalp and face so that when I first saw him on January 18, 1949, in the Out-Patient Department he appeared to be suffering from severe exfoliative dermatitis and complained of intractable pruritus.

General physical and special examinations.—The patient was well-developed slightly obese man of medium stature. His B.P. was 220/110. Heart sounds of good quality. Aortic second accentuated. Lungs—B.S. clear. Abdomen, liver and spleen not palpable.

The skin was red and somewhat indurated, and was shedding large sheets of thick scales.

Pupils: Equal reacting to L and A.

Discs: No papillœdema. Retinal arteries tortuous.

C.N.S.: N.A.D.

E.C.G.: Left axis deviation plus evidence of left ventricular strain.

X-ray of chest shows enlarged heart. Hypertensive type.

X-ray of both hands and feet normal.

Laboratory data: Urine normal on several examinations. Blood urea 30 mg. per 100 c.c.

Blood counts.—10.2.49: R.B.C. 5,270,000; Hb 100%; C.I. 0·96; W.B.C. 9,600. Differential: Neutros. 64%, eosinos. 1%, monos. 3%, lymphos. 32%.

7.12.49: R.B.C. 5,200,000; Hb 85%; C.I. 0·81; leucocytes 5,200. Differential: Neutros. 70%, monos. 4%, lymphos. 26%.

Treatment.—Rest, sedation for pruritus. Antihistamine drugs and local applications—calamine and hydrarg. perchlor. 1:10,000. Vitamins A.B.C.D., &c.

He was discharged from hospital on 14.2.49 very much improved.

As the pruritus often worried him at night and the skin retained its red hue with areas of small scaly patches on the trunk the patient continued to attend O.P.D. for observation.

In May a nodule appeared on the back of left hand—excision (Histological report—Epithelioma).

Later subcutaneous nodules were noticed on back of both hands and forearms. These have gradually increased in size and are now about the size of marbles.

Biopsy of a nodule (Histological report *see below*).

In June the pruritus again flared up. The patient was kept on vitamins, antihistamine, and in addition was given a course of B.A.L. An improvement was noticed in the skin which now no longer sheds, and the pruritus has disappeared. The redness and induration have, however, remained.

Short review of literature.—The exact nosological position of mycosis fungoides is still far from settled. The non-characteristic clinical and histological picture of the early premycotic phase lasting for weeks or years does not help in diagnosis.

Besnier [1]: "A chronic ambiguous pruritic dermatitis rebellious to ordinary treatment, and which assumes the form of a vague erythrodermia, &c. It is always necessary to bear in mind the question of a possible mycosis fungoides."

Ewing [2] stated that "mycosis fungoides is a reticulum cell lymphosarcoma originating from reticulo-endothelial cells".

Frazer [3] believed that "inflammatory reactions observed during the premycotic stage are due to the developments of tumour cells".

Montgomery [4] states that the histopathological changes in the early premycotic stage are inflammatory, and only later on that transition to lymphoblastoma becomes apparent.

Hynes [5] reported "An associated squamous cell carcinoma of face"—in his case of mycosis fungoides.

Histological report (Dr. C. N. Partington).—Section shows an inflammation of the skin. There is an acanthosis involving chiefly the interpapillary processes which have become lengthened. The stratum granulosum is not well defined and in places absent and the cells replaced by parakeratotic horn cells. The papillar and subpapillary vessels are dilated and surrounded by zones of lymphoid cells. The leucocytes have in places found their way to places between the prickle cells and some are collected superficially. The appearances are consistent with psoriasis. There is no evidence of Hodgkin's, or leukæmic infiltration. The appearance is not that of a *typical* mycosis fungoides.

In view of the history and the findings I think it advisable for me to send the slide with notes to Dr. W. Freudenthal, Reader in Dermatological Histology, University of London.

Histological report (Dr. W. Freudenthal).—The histological diagnosis rests between psoriasis and the pseudo-psoriatic picture that is frequently produced in mycosis fungoides (or rather premycosis) when the infiltrate in the uppermost layer of the cutis presses

against the epidermis and elongates the papillæ. I would prefer the latter diagnosis: the infiltrate is somewhat denser and more numerous than usually found in psoriasis, it also reaches deeper down and does not always seem to be connected with the epidermal changes. Generally, one gets rather the impression of a cutaneous process producing secondary epidermal changes than of a true epidermo-dermal process, as in psoriasis. Though the biopsy, in my view, is in accordance with and supporting the clinical diagnosis of mycosis fungoides (or an allied reticulosis), you were fully justified in raising the question of psoriasis as a differential diagnosis, and I agree with you that histologically psoriasis could probably not be entirely excluded.

SUMMARY

(1) A case of mycosis fungoides is presented.
(2) Mycosis fungoides may follow in the wake of any chronic scaly erythrodermia.
(3) Biopsies show epithelioma of the hand, and mycosis fungoides.
(4) B.A.L. may have been a placebo, but the itching in this case has disappeared since its administration.

Dr. James Sommerville: There are two forms of approach to the treatment of this case. One is a nitrogen mustard preparation and the other is "shower bath" X-ray therapy. For the former I have an intense dislike, and the results are unsatisfactory. The second has to be undertaken with very great care because it is extremely severe on the patient. These patients have to be "hit" hard enough to produce a very sharp blood reaction. Four equal fields are taken, to each field up to 200 r is applied, and the blood count checked daily. When a certain stage is reached I have no doubt that the patient will improve clinically very markedly for quite a time, depending on the extent to which he can stand up to therapy. The first case of the kind, reported by me in the *British Journal of Dermatology* thirteen years ago, is still alive and in good health. The man has survived two attacks of exfoliative dermatitis.

The President: What is the advantage of using a high kilovoltage?

Dr. Sommerville: The kilovoltage used is 150–200. The high kilovoltage acts more quickly. We have used lower kilovoltages but have not got the same results.

Dr. Brian Russell: I believe that the local application of thorium-X is the treatment of choice until tumours develop, when X-rays are usually necessary. Thorium-X keeps the patients relatively comfortable and can be applied with ease and safety to extensive and patchy lesions without the risks associated with X-ray exposure over a wide area.

Dr. C. H. Whittle: Dr. Sommerville has deprecated the use of nitrogen mustard. Reports in the literature vary with regard to the effect of this preparation. Can he tell us more about it? I admit that in asking the question I am thinking also of my own case of ? reticulosarcoma.

Dr. Sommerville: I believe that with more recent methods of using nitrogen mustard it is probably safer than it was in the not too distant past, but in Glasgow we have had one or two abrupt terminations of the treatment, and these have rather frightened me. More recently the results have been better because of the tests carried out beforehand, but I do feel that nitrogen mustard is the last card that should be played. Mycosis fungoides is very radio-sensitive, and results are observed early.

Dr. A. C. Roxburgh: I treated a case of severe mycosis fungoides with malaria during the war. He had about twelve paroxysms of malaria and was pretty ill with it, but his mycosis fungoides cleared up and he was well four years later although not entirely free from eruption.

Morphœa-like Paraffinoma Medicamentosa.—BRIAN RUSSELL, M.D.

Mrs. H. C., aged 58.

History.—At age 19 she had scarlet fever, followed by exophthalmic goitre, for which she received injections on alternate days in the arms. Some time after this, thickening appeared at the sites of injection and has persisted.

At age 24 she had an operation for goitre. Her voice has been hoarse ever since.

At ages 33 and 40 she had pneumonia.

At age 51 she had an operation: right cervico-thoracic preganglionic section, for Raynaud's phenomenon and sclerodactyly.

At age 52 similar operation, left. She also had Trendelenburg's operation to both lower limbs and injection of remaining varicosities.

At age 55 rheumatic pericarditis.

On examination (31.8.49).—Hard, shiny bands of a centrally golden and marginally pinkish colour on the outer aspects of both arms, just above elbow (Fig. 1). Several discrete, pea-sized nodules felt above the bands and a skin-coloured, tender nodule in the vaccination scar.

The patient also suffers from Raynaud's phenomenon, with atrophic changes at the tips of the fingers.

Investigations.—Wassermann and Kahn reactions negative.

X-ray examination—no cervical ribs.

X-ray examination of arms: There are multiple minute opacities veiling the soft tissues of both arms, situated posterolaterally to the lower third of the shaft of the humerus. The appearances suggest that an opaque substance had been injected in these areas (Fig. 2).

Blood count, E.S.R. and serum calcium within normal limits.

Histological report.—Paraffin section (H. and E.): Section shows the dermis to contain a number of clear spaces surrounded by a few chronic inflammatory cells and some fibrous

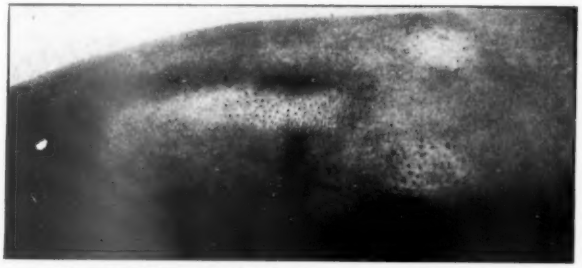

FIG. 1.—Morphœa-like band on outer surface of arm.

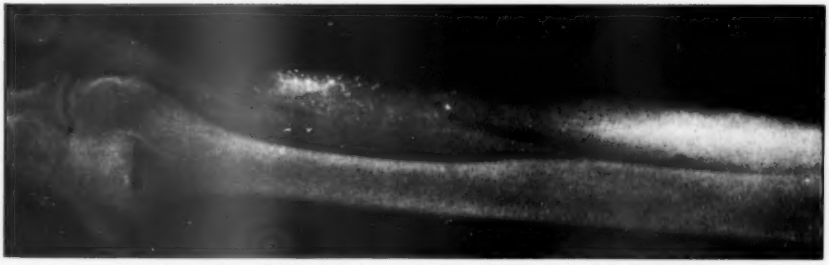

FIG. 2.—X-ray of arm showing multiple opaque globules in hypoderm.

tissue. In addition a number of foreign-body giant cells are seen, some of which contain vacuoles. The histological appearances are those of a foreign-body reaction.

Frozen section, stained with Scharlach R.: Section shows fat droplets in the circular spaces, with marked perifollicular concentrations, also around the sweat glands.

Dr. Russell: Paraffinomata may arise from the cosmetic or therapeutic injection of mineral oil. Vaseline is the more common cause on the face and camphorated oil on the arms, thighs, and breast.

This patient was seriously ill with exophthalmic goitre when she was given these injections, probably camphor in a mineral oil, or an iodized oil. Mook, W. H., and Wander, W. G. (*J. Amer. med. Ass.*, 1919, **73**, 1340–1341) described camphorated oil tumours and their clinical and histological appearances with illustrations to which this patient closely corresponds. The reaction is said to become noticeable first about one month after the injection.

Microscopically there are oval and round cavities, fibrous bands and multinucleated cells, the so-called "Swiss cheese" picture. The injected substance, although at first a discrete mass, is soon split into small parts by the growth of connective tissue trabeculæ into it. A similar histology has been reported in the lungs from the inhalation of oils used in nasal sprays, or from the accidental inhalation of liquid paraffin (paraffin pneumonia).

Miliary Acneiform Tuberculide, with Recent Mantoux Conversion.—BRIAN RUSSELL, M.D.

Miss J. D., aged 29. Nursing sister.

History.—May 1949, noticed a non-itching eruption on the forehead, cheeks and chin.

On examination (4.10.49).—There were semi-translucent, pin-head, yellowish follicular lesions, some flat, others slightly raised, on the chin and cheeks and to a lesser extent the forehead. There were no comedones (Fig. 1). The chest and back were clear. A tentative diagnosis of lymphocytomata was made.

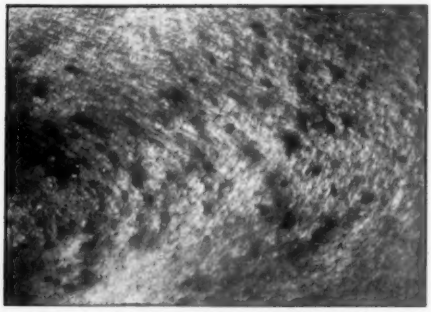

FIG. 1.—Semi-translucent lupoid nodules on side of chin.

Personal history.—Is an only child. Father has pulmonary tuberculosis.

It is known that in 1946 the patient's Mantoux reaction was negative.

December 1948: She suffered from anorexia and loss of weight.

February 1949: An X-ray of the lungs revealed an inexplicable shadow in the right lower lobe which was not found on re-examination.

April 1949: The Mantoux reaction was found to be positive.

Investigations (18.10.49).—Mantoux examination 1: 100,000 positive (erythema 1 inch by ¾ inch, with slight thickening at forty-eight hours).

E.S.R. : 3 mm. in one hour.

X-ray of chest : No abnormality detected.

Histological report (Dr. G. Cunningham, 15.10.49).—Section shows the presence of a follicular granulomatous reaction in the dermis in which giant-cell formation can be seen. There is no evidence of caseation and the Ziehl-Neelsen section is negative for tubercle bacilli. While a diagnosis of Boeck's sarcoidosis is a possibility, the histological picture suggests that a tuberculide or lupus vulgaris is more likely.

Porokeratosis of Mibelli.—H. T. H. WILSON, M.R.C.P.

Mrs. E. B., aged 51.

Family history.—Father alive and well. Mother died—coronary thrombosis. 6 sisters and 1 brother alive and well. 1 brother killed in a mining accident. No family history of skin disease.

Past history.—Measles and whooping cough in infancy. Scarlet fever when aged 18. Edentulous—all upper teeth removed when aged 19, lower teeth removed when aged 39.

History of present complaint.—The present lesion began about ten years ago as a small, slightly painful fissure at the left corner of the mouth. It has since enlarged very slowly and now presents as a semicircular patch of atrophic skin extending outwards and upwards from the angle of the mouth, and inwards for a short distance on to the buccal mucosa. A narrow horny ridge surrounds the atrophic area and separates it from the normal skin (Fig. 1).

FIG. 1.

Investigations.—Wassermann reaction negative. Meinicke reaction negative.

Biopsy (Dr. Haber).—There is a characteristic parakeratotic plug occupying the whole epidermal part of a sweat duct at the edge of the lesion. The sweat duct itself is dilated and funnel shaped. Towards the centre the epidermis is atrophic and the basal layer slightly hyperpigmented. The upper third of the corium exhibits senile elastosis, dilatation of vessels and mild chronic inflammation. The appendages appear to be normal. Porokeratosis (Mibelli).

Lupus Erythematosus and Rosaceous Tuberculide.—R. J. CAIRNS, M.R.C.P., for G. B. MITCHELL-HEGGS, O.B.E., F.R.C.P.

Mrs. L. H., aged 56.

History of present complaint.—Six years ago a red, scaly patch about 1 cm. in diameter developed on the tip of the nose. She was seen by Dr. Muende who diagnosed lupus erythematosus and advised the local application of carbon dioxide snow and a course of gold treatment. Under this treatment the lesion cleared until fifteen months ago when the eruption recurred.

About nine months ago an entirely different eruption appeared consisting of small groups of pin-head-sized papules on an erythematous background on the sides of the cheeks and upper part of the sides of the neck. Since this time the erythema has faded but the papules have persisted and are increasing in number.

The general health is good. The menopause occurred seven years ago.

Past and family history.—Nothing relevant; no tuberculosis.

On examination.—On the tip of the nose is a white atrophic scar 1 cm. in diameter with a telangiectatic margin. Above this is a similar area. There is no scaling or follicular plugging. There is a white area in the right lower molar region with ulceration.

Scattered widely over the cheeks, sides of the face and upper part of the neck are closely set pin-head-sized papules, brownish yellow in colour. On diascopy the colour is more yellow.

There is no evidence of erythema, pustulation or telangiectasia in association with these papules. The centre of the face shows no papules. The skin elsewhere is unaffected.

Investigations.—Chest X-ray clear; B.S.R. 10 mm. in one hour; Blood: Hb 100%. Cell count normal; urea 38 mg.%; W.R. and Kahn negative.

Biopsy report.—"The epidermis shows some parakeratosis and there is a decrease in the depth of the rete pegs. In the corium there are foci of necrosis with surrounding endothelioid cells. In these foci there is a loss of elastic fibres. External to the collections of endothelioid cells there are lymphocytes. The latter are also present in relation to small blood vessels of the corium. There are a very few giant cells of the Langhans type in relation to the proliferating endothelioid cells. No acid-fast bacilli seen."

Mantoux—6.7.49 : Negative at 1 : 1,000; 10.10.49: Positive at 1 : 1,000; 14.11.49: Slightly positive at 1 : 10,000.

Treatment.—Calciferol 100,000 units daily. Tabs. Ephynal 50 mg. t.d.s.

Comment.—The interest of this case is that a patient with inactive chronic discoid lupus erythematosus developed what appeared to be clinically a rosaceous tuberculide. Histologically there is necrosis and the lesions are deeper than those in the rosaceous tuberculide. There is, however, no marked tuberculin sensitivity as one would expect with a papulonecrotic tuberculide.

I should like to draw attention, however, to the fact that a rise in tuberculin sensitivity occurred which might be related to the development of a tuberculide.

Pemphigus of the Mucous Membranes with Symblepharon.—LOUIS FORMAN, M.D.

Married woman, aged 68.

Ulceration of the mouth, nose, throat and vulva for five years and of the eyes for eighteen months. She states that a raw area appeared round the umbilicus two years ago which lasted some months. Four years ago there was a raw area on the front of the right shin.

From September 1948 to February 1949 she was in the Middlesex Hospital under the care of Professor A. Kekwick who says: "She showed injection of the conjunctivæ of both eyes with chemosis, intense hyperæmia and superficial ulceration of the buccal surfaces of the cheeks, fauces, and vulva. There was a history of nervous breakdowns in the past. She was observed to rub the affected parts most of the night. The arms were kept in plaster and the eyes covered for six weeks, but no improvement was noticed. She had certain morbid fears of becoming a mental case and in 1948 became mildly delusional.

"It had been thought for some time that the lesions were artefacts and in view of her failure to improve with medical treatment it was decided to do a prefrontal leucotomy. During the succeeding two months there was general and local improvement but she subsequently relapsed."

There is now an almost complete symblepharon, and ulceration of the mucous membrane of the cheeks with areas of bulky pyogenic membrane. There is persistent superficial ulceration of the inner surfaces of the labia, with much complaint of irritation. Nikolski's sign was negative. No porphyrins were present in the urine. Capillary resistance was not diminished.

Although shown under the accepted title of pemphigus of the mucous membranes the case appears to belong to the group of acquired epidermolysis bullosa occurring in aged patients. The differentiation between these two conditions in the aged is often difficult. Thus in epidermolysis bullosa, blisters have occurred in the conjunctivæ and appeared spontaneously on the skin. Positive iodide tests have been reported by Sulzberger in a hereditary case of epidermolysis bullosa. Barber and Gougerot have described patients who presented grouped irritable blisters recalling dermatitis herpetiformis and who subsequently were thought to be examples of epidermolysis bullosa.

The following cases were also shown:

Benign Erythematoid Epithelioma (Graham - Little).—Dr. C. H. WHITTLE and Dr. R. E. CHURCH.

Pustular Psoriasis.—Dr. H. W. ALLEN.

(These cases may be published later in the *British Journal of Dermatology*.)

ADDENDUM

Cases and Discussion on Familial Benign Chronic Pemphigus

pp. 61–65, *Proceedings*, Vol. **43**, February 1950. (Meeting held October 20, 1949.)

The following communication has been received from Professeur H. Gougerot, Médecin de l'Hôpital St. Louis, Membre de l'Académie de Médecine, 26, Boulevard Raspail, Paris:

Profitant du rayonnement du Congrès de Bruxelles-Liège de 1949, je me permets de faire une revendication de priorité au sujet de ce pemphigus. En effet j'ai décrit cette dermatose bulleuse (avec Allée) dans les *Archives Dermato-Syphiligraphiques de la Clinique de l'Hôpital St. Louis* (Juin 1933), **T. 5,** page 255, donc plusieurs années avant Hailey-Hailey (dont la publication est d'Avril 1939) et même avant l'observation allemande de Hübner d'Avril 1937, citée par Balter dans sa *Revue Générale des Annales de Dermatologie et de Syphiligraphie* (*Françaises*) de Juillet 1947 (T. **7,** page 243).

Notre observation était caractéristique: "Pemphigus familial héréditaire congénital; un enfant de quatre ans atteint dès sa naissance, père de 38 ans, cousin germain de son père et le fils de ce cousin, âgé de 19 ans, atteints de la même façon; bulles annoncées par du prurit souvent intense ou par des cuissons; évolution courte de chaque bulle, mais répétition incessante des bulles; frottement et pression facteurs déclenchants."

Section of Radiology

President—S. COCHRANE SHANKS, M.D., F.R.C.P., F.F.R.

Churchill Hospital, Oxford, England

[*November* 18, 1949]

DISCUSSION ON THE CHEMICAL FACTORS MODIFYING RADIOTHERAPEUTIC RESPONSE

Dr. Frank Ellis (London Hospital): Radiotherapy is in its third stage of development. The first stage was one of empiricism both as regards dosage and biological observations. The second saw the establishment of a unit of dosage and the development of physical methods for measurement so that chemical and biological results could be compared. Now we are achieving some degree of understanding of the chemical effects of radiation and a wider knowledge of the way in which radiation has its effects on living tissues. As a result of this increasing comprehension we may hope to use radiation with more insight so that the margin between the tolerance of normal tissues and the sensitivity of malignant cells to radiation may be increased, and we may attempt to condition malignant cells so that they are destroyed by smaller doses of radiation than are now used. The two methods available to us are the adjustment of the time-intensity relations of methods of treatment and the use of chemical substances. Both these devices must be dependent on the mode of action of penetrating radiations.

The action of ionizing radiations is not specific and in aqueous solutions most of the energy is absorbed in the solvent. The number of molecules of solute changed by the radiation is proportional to the number of ion-pairs formed by the radiation and thus to the dose of radiation absorbed (Fricke, 1934; Dale, 1942). This was demonstrated by Dale using purified enzymes in dilute solution and led Allsopp (1944) to suggest that the radiation produced its effect on the enzymes through activation of the water. From the activated water molecules the solute receives the energy which results in detectable chemical change. The presence of some other substance in solution either independent of, or derived from, the original substance may protect the latter from the effect of the radiation, and the amount of change which it undergoes is no longer linearly proportional to the dose absorbed but follows an exponential law as was shown by Dale. He was able to demonstrate the different protective effects of various organic and inorganic substances. With very low or very high concentrations, also, the effect is not proportional to dose because some of the "activated water" does not meet with a solute molecule in the first case, and because an appreciable proportion of the solute molecules is affected directly by the radiation in the second case. The hypothesis that the formation of hydrogen peroxide was the responsible factor was disproved by the demonstration that the yield of hydrogen peroxide when water is irradiated could only take place in the presence of dissolved oxygen, but was not dependent on the amount of oxygen dissolved. Weiss (1944) suggested that the water is decomposed by radiation into hydrogen atoms and hydroxyl radicals, and Lea (1947) has given us quantitative estimates of the relative distribution of the hydrogen and hydroxyl radicals. The important point is that owing to the relatively great distance which an electron travels from the site of ionization, as compared with the path of the positive ion, the resultant radicals are differently distributed and so do not recombine at once to form water. It has been shown (Wegmuller, 1942) that ethylene bromide and also thymonucleic acid can only be affected by radiation in the presence of a certain minimum amount of water representing thousands of molecules of water to each molecule of the dissolved substance. Read (1948) has suggested that if an ionizing particle

passes through a chromosome the separation of charge may give rise to tensions of the order of 10^5dynes/cm^2 along the chromosome which might produce breaks at weak points. Chromosome breaks have been demonstrated histologically and Lea (1946) has demonstrated the validity of the target theory for these effects of radiation although the chemical theory also fits the facts. Perhaps there is no fundamental divergence between the two theories if one assumes that a hydroxyl radical set free within a certain definite neighbourhood of a chromosome is a "hit". In any case Waters (1947) has suggested that a molecule will break, not necessarily at the point of initial absorption of energy, but at its weakest point. He also considers that radicals such as the OH radical might be quickly changed in type so as to have less free energy and therefore more selective action. Reactions with OH, NH, SH and C=C groups are known to occur. Further he does not consider that any active radicals produced outside a cell would enter it. They would react with the cell wall. Nevertheless radiation can produce radicals inside the cell and even by direct action, in an enzyme, which might result in an abnormal type of enzyme giving rise to abnormal reactions. These reactions provide a reasonable mechanism for chromosome changes both visible and invisible, and for cytoplasmic changes both primary and secondary to other changes in the cytoplasm and in the cell membrane. The changes in appearance of cells and their behaviour at mitosis follow on the above changes. Certain specific facts have been observed, both chemical and histological, which might indicate the way in which chemical factors will influence response to radiation. For instance it has been shown (Frilley, 1947) that in addition to the yield of H_2O_2 by radiation of water being increased as a result of the presence of dissolved oxygen, there is also a systematic increase with rise in hydrogen-ion concentration (i.e. increased acidity), and with the presence of reducing substances such as hydroquinone, cysteine and ascorbic acid and a diminished yield in the presence of organic acids. Moreover the irradiation of water containing oxygen results in a higher H -ion concentration. Methylene-blue reduction occurs with radiation and is hindered by the presence of dissolved oxygen (Loiseleur, 1947). Tyrosine, deoxyphenylalanine and certain other substances have been shown to undergo oxidation with doses up to 500,000 r. Deamination of amino acids (glycine, alanine and serine) has been demonstrated (Stein and Weiss, 1948*b*) in the absence of oxygen, resulting in ammonia, aldehyde and keto-acid formation such as result from biological oxidation of such acids by enzymes. Also, the addition of oxygen to benzene rings has been demonstrated under anaerobic conditions as a result of radiation (Stein and Weiss, 1948*a*). These experiments prove the formation of OH radicals in water by radiation. In the presence of oxygen the amount of oxidation is increased. The amount of chemical change in certain reactions can be measured colorimetrically and is proportional to dose over a range from 0–50,000 r (Farmer and Weiss, 1948) suggesting that it might be used for dosimetry. The protective effect of a sulphur atom in a molecule is shown by Dale (1947) in the contrast between the protective action of thiourea and that of urea for carboxypeptidase irradiated in solution. Substitution of the oxygen of urea by a sulphur atom increases the protective effect about 2,400 times. This may be of significance when we consider the importance of sulphydryl groups in biological reactions.

Local biological observations. Mitotic inhibition and degeneration.—It has been shown by Spear and his co-workers that radiation in small doses inhibits mitosis and causes degeneration of cells. The inhibition of mitosis can be correlated with the observation by Mitchell (1943) of the inhibition of the production of thymonucleic acid by the enzymes in the nucleolus as a result of radiation. This seems to be a temporary rather than a destructive effect. The degeneration of cells is presumably due to irreversible changes of unknown nature but Wilson *et al.* (1935) consider that this effect is enhanced in growing tissue with a blood supply and appears at the same time as the blood supply degenerates. They consider that the loss of nutrition is responsible. It may be that this is the case, but the possibility of simultaneous changes occurring in both blood vessels and the tissues they supply, both primarily due to the radiation, is also a possibility as well as degeneration following lack of oxygen.

Diffusible substances.—Following the breakdown of cells the products of such breakdown must be set free in the tissues. Jolles (1949) has shown good evidence for the presence in irradiated tissues of a diffusible substance which tends to intensify X-ray reaction in an irradiated field separated from it by a certain distance depending on the size of the field. This fits in with the experience of all radiotherapists that a larger field, from which the passage of such a substance will be more difficult than from a small one, shows more reaction for the same dose and less rapid recovery for the same reaction than a smaller field. This must be a chemical effect. His attempt by means of a chess-board lead filter, to demonstrate an indirect effect of this substance on cancer tissue, is more open to criticism because there must be lateral scatter into the "protected" areas. Doubtless there is an indirect effect as well,

but whether it is cancerocidal rather than merely inhibitory as is the effect of direct radiation is not proved and seems unlikely.

Catalase has been shown to occur in increased concentration in the liver in malignant conditions in animals and in view of its function in destroying hydrogen peroxide such an increase might so interfere with the body chemistry as to affect the sensitivity of neoplasm to radiation.

Antibodies are chemical substances. It is thought as a result of the work of Fagraeus (1948) that antibodies are produced in plasma cells which are produced by more primitive cells in response to an antigen. It has been shown (R. G. White, 1949) that irradiation, shortly before an antigen is administered to a rabbit, inhibits antibody formation. If given three or four days afterwards, however, radiation does not inhibit the effect of a second dose of antigen in producing a secondary response, suggesting that the primitive parents of the plasma cell are sensitive but that the plasma cells are insensitive to radiation. In view of the plasma cell infiltration occurring around a malignant tumour one wonders if this is possibly an attempt to bring antibodies to the site by plasma cells which are produced by antigen set free by the break-up of treated cells.

Sepsis is, of course, helped by small doses of radiation, but interferes with the response to radiation of malignant disease. It may be that the inflammatory reaction competes with the malignant cells for the available oxygen thus diminishing the sensitivity of the dividing cells to the radiation.

Bean root tips and oxygen.—Read (1948) has shown that with a concentration of oxygen up to ·5 c.c. per litre the sensitivity of the growing root tips of the broad-bean to radiation is increased by increasing concentration of oxygen. This is true for both alpha and X-radiation, but the increase with alpha rays is less in proportion than with X-rays, the roots being about 20 times more sensitive to alpha rays with no oxygen, and 9 times more sensitive with 5 c.c./litre of oxygen and over. The oxygen favours inhibition of mitosis and production of abnormal mitoses also. He considers that the denser terminal and delta ray tracks of X-radiation and the dense tracks of the alpha radiation produce their own oxygen and thus give rise to HO_2 and subsequently to H_2O_2. The lack of oxygen in severe anæmia might affect the response of a malignant tumour to radiation.

Other substances.—Sulphonamides and other substances which may be given for other purposes might conceivably have an effect on the local response of a treated lesion.

Kelly (Kelly and Dowell, 1942) in his work on gas gangrene demonstrates a difference which is statistically significant indicating that X-rays and sulphonamides together give worse results in gas gangrene than X-rays or sulphonamides only.

Synthetic vitamin K and a series of acridine compounds have been shown to inhibit mitosis. The latter have also been shown to produce nuclear and cytoplasmic degenerations. Nitrogen mustards, trypflavine, urethane, acetone, carcinogens and the sex hormones have been shown (Hohl, 1948) to cause chromosome fragmentation, nuclear pyknosis due to accumulation of thymonucleic acid and injury to the centromere in cells and the changes are said to resemble those due to radiation. It has been suggested that nitrogen mustards cause chromosome bridging by a chemical linkage of two chromatids (Goldacre, Loveless and Ross, 1948) and that X-rays might do the same by oxidizing two S=H groups in adjacent chromosomes. Many of these substances, however, are toxic and are unlikely to be very effective in dealing with malignant disease because of the vulnerability of other dividing cells in the body.

The least toxic are the sex hormones and synthetic vitamin K.

Suggested application of the above chemical factors.—The cell is by evolution a relatively invulnerable structure. The nucleus of the cell is its least vulnerable part. The only difference between a normal and a malignant cell is in the urge of the latter to grow and divide, irrespective of the chemical restraint of surrounding tissues. Because of these facts I see little prospect of destruction of cancer cells by chemical substances given systemically without the destruction of other dividing cells in the body. Given in safe doses I expect growth restraint only. Radiation is likely to be the most selective agent because it can penetrate to the nucleus of the cells. As a first essential, therefore, we must aim at using radiation as effectively as possible.

Time intensity relations.—The effect of radiation on tissues is to damage all cells some of which break up or otherwise set free a substance or substances which are damaging to the organism and to the tissues in contact with it. The break up of cells and the amount of diffusible substance set free are both proportional to the dose. The aim must be to give a maximum number of röntgens to the malignant cells and to keep the concentration of diffusible substance to a minimum.

The diagrams show the possible behaviour of a toxic diffusible substance resulting from 1 fraction daily compared with 4 fractions daily: (*a*) with incomplete recovery between fractions (Fig. 1); (*b*) with complete recovery between fractions (Fig. 2).

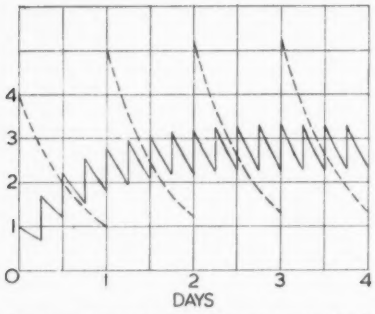

FIG. 1.—Type of cumulative concentration in the tissues of diffusible substance if disappearance of the substance between treatments is not complete. ("Half-life" = $\frac{1}{2}$ day, i.e. $\mu = 1{\cdot}38$.)

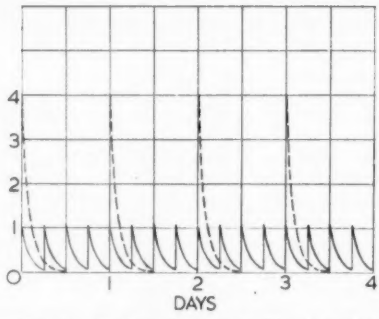

FIG. 2.—Similar diagram to Fig. 1 to show the relative concentrations if disappearance is complete. ("Half-life" = $\frac{1}{10}$ day, i.e. $\mu = 0{\cdot}17$.)

The toxic effect will depend on the concentration reached by the substance at any time and on the product of the concentration and the time for which it is present. The former is measured by the height of the curves in the diagrams and the latter by the area below the curves. It is seen that if recovery is complete the difference is one of concentration only (Fig. 2). If recovery is incomplete there is, in addition, a difference in dose of diffusible substance (Fig. 1) which is present, however, only during the first few days of the treatment. The concentration of the diffusible substance must always be less if there are more fractions, and the higher concentration is more toxic than the low one and is present for a longer time. Therefore the damage done is likely to be greater for the same röntgen dose. This may account for the slighter effects seen on normal tissues with protracted fractionation methods than with simple fractionation and with continuous or interrupted gamma ray treatment, requiring long exposure with low dosage rate, than with the high dosage rate of X-ray treatment. Thus by multiplying the number of fractions it should be possible to give many more röntgens. Gray's hypothesis (1944) suggests that for four times the number of fractions twice the dose can be given, i.e. instead of 4,000 r 8,000 r in one month. This hypothesis is related only to chromosome breaks. It is likely that the formation of a diffusible substance modifies the reaction, resulting in diminished tolerance with increased area and increased tolerance with increasing fractionation.

The larger the volume to be treated, provided one is not treating the whole of the hæmopoietic system, the greater the number of fractions which should be administered for a given röntgen dose.

Protection by radiation against radiation.—In view of the suggested antibody effect it is theoretically advisable to start with small doses of radiation and even possibly to allow an interval of a week or so to enable the antibody mechanism to become active against the tumour.

Radiation in large doses has been shown to protect animals against subsequent radiation. This is not justifiable in the case of human beings—even with the threat of an atomic bomb—unless it is possible to demonstrate that the reaction can be obtained safely. It may be that the production of a chemical substance in the skin is a factor in the protection and that some degree of immunity might be afforded by giving safe doses of non-penetrating radiation to the skin only. This possibility should be explored.

It is a not uncommon experience of radiotherapists to find that seven to ten days' rest from treatment of a patient, who at the end of one week's treatment appears to be tolerating a bath treatment badly, enables the patient to complete treatment to a high dose (e.g. 3,000 r in five weeks to the whole abdomen) without difficulty.

Giving chemical substances.—*Oxygen* is the obvious substance to use in view of the effect on the radiosensitivity of the bean root. I have injected hydrogen peroxide into the middle of a necrosing malignant gland which cleared up completely following a course of radiation. The injection was given just before treatment on each occasion.

Read's experiments show that the maximum sensitizing effect of oxygen is reached at

a tension of 5 c.c./litre. The following calculation shows how this might be attempted in the tissues:

In normal arterial plasma the oxygen dissolved is 0·3 c.c./100 c.c. = 3 c.c./litre. *Tension* = 90 mm.Hg.

Normally in the tissues the oxygen tension = about 40 mm.Hg.

∴ Dissolved oxygen = 1·3 c.c./litre in tissues.

In view of Read's work it seems that an increase in the amount of dissolved oxygen may increase all sensitivity to radiation.

By giving 90% oxygen during treatment, tension in alveolar air = about 700 mm.Hg. Tension in arterial blood = ? 630 mm.Hg, i.e. 21 c.c./litre.

Amount dissolved in tissues = ? 7 c.c./litre.

This will tend to increase the oxygen content at the site of malignant cells, especially when the blood supply is poor.

Hydrogen-ion Concentration

Higher H+ concentration causes increase in H_2O_2 production in water. Whether this can be influenced significantly is doubtful but CO_2 given with oxygen might help.

A meat diet (Paterson *et al.*, 1948) increases general sensitivity to radiation of mice and also tends to produce an acidosis. Whether this would apply to tumours also remains to be seen.

Synkavit.—Mitchell (1948) has shown a significant improvement in advanced cases of cancer treated with large doses of synthetic vitamin K in conjunction with radical and palliative X-ray treatment. The idea behind the method was by using a chemical substance to try to block the synthesis of nucleic acids by a different mechanism from that by which radiation does so. The substance causes inhibition of mitosis in tissue culture of fibroblasts and although gross structural changes are considered to be those of most importance in killing cells by radiation, the combined effect of the radiation and synkavit indicated significant reinforcement of the effects of radiation by the synkavit.

Clinical trials in 240 patients with various types of advanced malignant tumours showed that the compound, which is of low toxicity, is best given as daily intravenous injections. In 130 cases it was given intramuscularly and in 110 cases intravenously. Focal pain or focal sensation in the region of the tumour were a common result of large intravenous doses. Mitchell attributes this to temporary cell œdema. Clinically a small but useful improvement in palliative results is shown by about one-quarter of all the cases of advanced cancer treated by this method and a small but significant increase in survival time with X-ray treatment in inoperable histologically proved cases of carcinoma of the bronchus. Retrogression of tumour cells has been demonstrated histologically by synkavit alone in certain cases of adenocarcinoma. Using ultraviolet photomicrography it has been shown to produce chromosome fragmentation different in appearance from that produced by X-rays. Mitchell and his group have used tissue culture methods to study the antimitotic activity of other substances and it has been shown that the mitotic inhibition produced by some quinones and maleic acid parallels the interaction with –SH compounds. It seems to me that this compound synkavit might inhibit mitosis by a selective blocking of important chemical –SH groups in the cell and that it might help the effect of X-rays by preventing these –SH groups from "protecting" the substances in the cells on which the effect of X-rays is most damaging. As already mentioned, thiourea has been shown by Dale to be very protective and it contains a sulphur atom, its only difference from urea which is a very inefficient protector.

Other substances which act as protoplasmic poisons such as urethane, nitrogen mustards and acridine derivatives might also have an effect on malignant cells which would reinforce the effect of X-rays. Certainly, in the doses in which they have commonly been used, hitherto, it would be folly to try to combine them with radiation, but there is room for clinical experiment with smaller non-toxic doses so that the essential body tissues such as hæmopoietic tissue are not unduly affected. Laboratory investigations of the type being directed by Professor Mitchell would indicate whether these substances offer any hope of an action similar to that of synkavit. Professor Mitchell told me that synkavit-treated cases tend to develop an early severe reaction with X-rays. My experience with patients who have developed such a fierce early reaction with X-ray treatment only is that they do much better than one would expect—and that with a dose only about half of the usual intended dose of radiation. It may be that such patients have in their tissues some such chemical sensitizer. Two at least of such patients who recovered completely from extensive lesions, with no obvious residual normal tissue changes, were very much addicted to beer. Following up such a clue might be worth while.

As in all biological work, clinical radiotherapy is a very difficult subject in which to be sure of a true comparison between cases. Because of this, conclusions are hard to draw, except from large series of cases, but even these must be carefully watched. Synkavit is

not a common vitamin to be given routinely, but many of the other vitamins (especially pyridoxine) are commonly administered for radiation sickness. We cannot say definitely whether they have any effect on the radiosensitivity of tumours. Again, the powerful antibiotics such as sulphonamides and penicillin might have more far-reaching effects in this respect than we have hitherto supposed. The important point which arises here is that, to ensure that wrong conclusions are not drawn subsequently from the statistical analysis of results, the exhibition of certain substances known to have important specific effects on living tissues should be carefully recorded in the radiotherapy notes in adequate detail, and also a record of the hæmoglobin during treatment should be kept because of the possible importance of oxygen. It is essential that controlled tests should be carried out to evaluate the effect, if any, of the many substances which may be administered to patients as supposedly without effect on radiosensitivity.

Hormones are in a similar position. They are all produced normally and a balance is maintained between the various endocrine secretions. The maintenance of this balance is thought to be the function of the pituitary gland.

We all know that a thyrotoxic patient has a more radiosensitive skin but we know nothing about the relative radiosensitivity of tumours in the presence of excess of thyroxin.

The administration of testosterone and synthetic œstrogen is a useful method of influencing some malignant growths, especially of the breast and the prostate.

I am reasonably sure that stilbœstrol improves the response of some tumours to radiation; a useful factor in dealing with ulcerating breast cancer. But the effectiveness of both testosterone and stilbœstrol diminishes as they continue to be used. It seems that this might be partly, at any rate, due to the controlling influence of the pituitary. How may such influence be established and used to help us in treating cancer? The growth hormone originates in the eosinophil cells of the pituitary and may influence cancer growth. No one knows if it has any influence on sensitivity to radiation of the malignant cells. Döderlein of Munich used to irradiate the pituitary routinely in treating cases of cancer of the cervix uteri (League of Nations publication on Carcinoma of the Cervix) and a case has been mentioned to me in which irradiation of the pituitary improved the radiosensitivity of a tumour (Binnie, pers. comm.). Some technique for testing the effect of such substances and procedures clinically is obviously required. Methods which suggest themselves are tissue culture and bean roots in the laboratory, and the use of P^{32} uptake as an index of growth activity in clinical work.

Chemotherapy of cancer has been developed during recent years and so far has been disappointing. I think this is inherent in the nature of the nucleus of the cell and the similarity of malignant and normal cells. Malignant cells differ only in the fact that they multiply with no regard for the needs of the body as a whole and the nucleus of any cell is likely to be relatively invulnerable to chemical substances so that a permanent, complete systemic destruction of cancer by such substances seems to me improbable. There is a case for combining radiation with effective chemotherapeutic substances which might enable adequate destruction of cancer in larger volumes with smaller doses of radiation than are necessary without such reinforcement.

The general effects of radiation due to, and influenced by, chemical factors are a very important aspect of this subject but it cannot be dealt with in this present discussion.

Dr. L. A. Elson (Chester Beatty Research Institute, Royal Cancer Hospital): *The influence of the protein content of the diet on the response to radiation of tumours in the rat.*—These investigations of the effect of diet on the response of tumours to radiation were the outcome of the discovery that the body growth- and tumour growth-inhibitory action of carcinogenic chemicals is profoundly influenced by the protein content of the diet (Elson and Warren, 1947; Elson and Haddow, 1947; Elson, 1948, 1949). In rats maintained on a 20% protein diet, injection of the carcinogen usually has little immediate effect on body growth, but a delayed action generally resulting in rapid loss of weight which may lead to the death of the animal often occurs later. Animals maintained on a 10% protein diet, however, usually show an immediate growth-inhibitory response to treatment with the chemical.

Implanted Walker Rat Carcinoma 256 shows a similar effect of diet on its response to growth-inhibitory chemicals. This effect is seen most strikingly in a type of experiment in which the inhibitor is administered in a single dose given about twenty-four hours after implantation of the tumour and the animals killed about fourteen days afterwards, the tumours being then dissected out and their weights compared with those of similar tumours in control, untreated animals. In one experiment of this type, using the carcinogenic, growth-inhibitory 2′-chloro-4-dimethylaminostilbene (150 mg./kg.) the average tumour weight in a group of 9 control animals maintained on a 20% protein diet and killed eleven days after the tumour implantation was 12·2 grammes whilst the average tumour weight in the treated groups was 11·4 grammes. Thus little tumour-inhibiting action of the compound is observed in animals maintained on this high protein diet, the ratio of the average weight of tumours in control animals to average weight of tumours in treated animals $\left(\frac{C}{T}\right)$ being 1·1. In similar groups of animals treated under the same conditions except for being maintained on a low (5%) protein diet the weights of the tumours of the control animals were very little different from those of the controls in the 20% protein diet group, the average weight being 11·6 grammes. The tumours of the treated animals in this 5% protein group, however, showed a very marked inhibitory effect of the chemical and only attained an average weight of 0·6 gramme, giving a ratio $\frac{C}{T} = 19{\cdot}3$ (Elson, 1949). Fig. 1 shows a photograph of the tumours obtained in another experiment with two groups of rats both treated with this same compound,

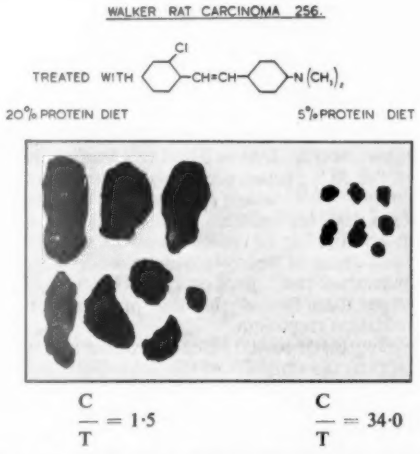

FIG. 1.—Tumours from rats treated with 2′-chloro-4-dimethylaminostilbene (150 mg./kg. i.p.) twenty-four hours after tumour implantation. Animals killed fourteen days after tumour implant.

but the tumours on the left are from the group maintained on a 20% protein diet, whilst those on the right are from the group maintained on a 5% protein diet. (The control tumours which again grew to about the same size in both groups of rats are not shown here, but the $\frac{C}{T}$ ratios are given.) This protective effect of diet has been observed with all types of tumour-inhibiting chemicals so far tested, including the so-called "radiomimetic" substances such as the nitrogen mustards, and suggests that the cause of their growth-inhibiting action may be an interference with the availability or with the synthesis of proteins necessary for growth.

Little is known of the actual mechanism of protein synthesis, but it has been suggested that it may be closely linked with nucleic acid metabolism (Caspersson, 1947). Following this suggestion it was found that the growth-inhibiting hydrocarbon 1 : 2 : 5 : 6-dibenzanthracene when injected into rats caused an increase in the ratio of pentose nucleic to deoxypentose nucleic acid in the liver, as a result of a fall in concentration of the latter (Elson and Harris, 1947).

An initial decrease in cellular deoxypentose nucleic acid was found by Stowell (1945) after X-irradiation of transplanted mouse mammary carcinoma and Mitchell (1942) from investigations of human tumours treated by X-radiation considered that an effect of the radiation was to inhibit the conversion of pentose nucleic to deoxypentose nucleic acid.

There appears therefore to be considerable similarity between the action of chemicals and radiation in this respect and an investigation of whether the profound effects of diet on the response of tumours to chemicals are also evident in their response to radiation appeared to be of considerable practical and theoretical importance. A preliminary study has now been carried out in collaboration with Dr. L. F. Lamerton.

Whole body X-radiation.—A first experiment was to try the effect of whole body radiation on rats implanted with Walker Carcinoma 256 under conditions approximating to those used in the experiments with chemicals. With a daily dose of 100 r per day for eight days the ratio $\frac{C}{T}$ when the rats were killed after eleven days was 2·9 for the group maintained on the 20% protein diet and 5·7 for the group receiving the 5% protein diet.

A similar greater response of the tumours in those animals receiving the low protein diet was thus also observed in the radiation treatment although the actual degree of inhibition was not as great as can be obtained with some chemicals.

The great advantage of X-ray treatment, however, is that it can be applied directly to the tumour in doses much larger than could be tolerated if applied to the whole animal, and the effect of diet under conditions which approach more nearly to those used in radiotherapy of human cancer comprised the main part of the investigation.

Direct irradiation of established tumours.—For these experiments the tumours were allowed to grow untreated for six days after implantation. Daily estimates of the size of the tumours were then made by measurement with calipers along two axes at right-angles. The estimate of the area (sq. mm.) obtained by multiplying these two figures was plotted against the number of days after implantation to show the progress of growth of the tumour.

For the radiation experiments tumours were selected which had reached approximately equal sizes (350 mm.^{2}–450 mm.^{2}—six days after implantation).

Control tumours in animals maintained on both high and low protein diets thus selected usually grow to a size of about 2,000–3,000 mm.^{2} in seventeen to twenty days when death of the animal occurs.

A total dose of radiation of 4,000 r was used and, in the first experiments, this was applied in daily doses of 250 r. The results (Fig. 2, *from* Elson and Lamerton, 1949) show, in the group of 4 animals maintained on the 20% protein diet, only a slight retardation of tumour growth compared with that of controls. The average survival time of the animals was twenty-eight days compared with nineteen days for controls. The group maintained on the 5% protein diet showed almost complete inhibition of tumour growth for a considerable time but eventually the tumours developed areas of necrosis which usually become infected but growth may be resumed before the death of the animal occurs. The average survival time, forty-four days, was considerably longer than that of the high protein group. No animal in either group was cured by this radiation treatment.

The dosage rate was then increased to 400 r per day whilst still maintaining the total dose at 4,000 r. Under this treatment the tumours of the animals maintained on the 20% protein diet at first grew more rapidly than those of the 5% protein diet group. Soon, however, these 20% protein diet group tumours ceased to grow and began to decrease in size and in 3 out of 5 animals eventually regressed completely by a "shelling-out" process. The other two showed partial regression but eventually grew again. In the group of animals maintained on the 5% protein diet only one tumour out of 5 regressed whilst the others grew at a much reduced rate, eventually resuming a more rapid growth rate before causing death.

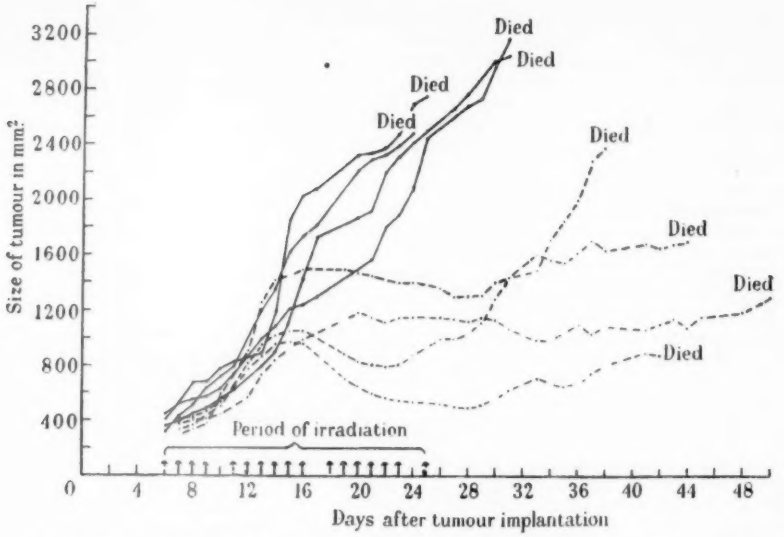

FIG. 2.—Growth of Walker Rat Carcinoma 256 treated with X-radiation; 250 r per day, total dose 4,000 r.

Continuous line Rats fed on 20% protein diet.
Interrupted line Rats fed on 5% protein diet.

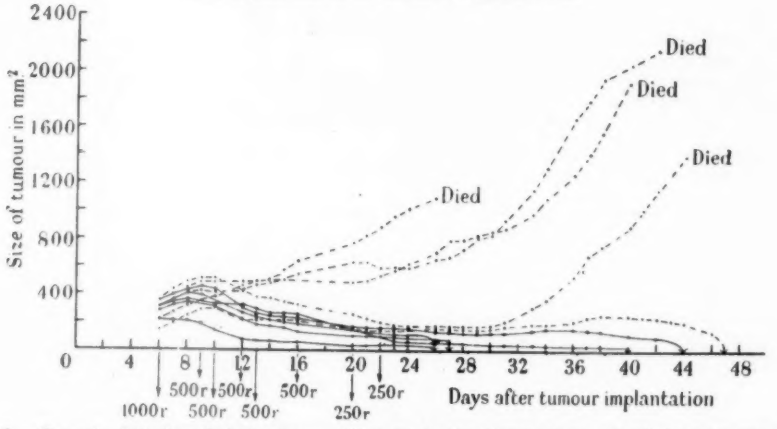

FIG. 3.—Growth of Walker Rat Carcinoma 256 treated with X-radiation; extended treatment with initial high dose (1,000 r); total dose 4,000 r.

Continuous line Rats fed on 20% protein diet.
Interrupted line Rats fed on 5% protein diet.

Figs. 2 and 3 are reproduced by permission of the Editor, *British Journal of Cancer*.

It seems therefore that although the growth-retarding action of radiation may be greater when the animals are maintained on a low protein diet, the degree of tumour regression and ability of the animal to rid itself of the tumour may be favoured by a high protein diet.

This idea was pursued in experiments increasing the daily dose rate to 600 r and changing the diet of the 5% protein group to 20% protein at the commencement of radiation. A daily dose of 600 r over seven days (to keep the total dose at approximately 4,000 r) was found, however, to be approaching the limit of tolerance of the animal for the radiation and the period of treatment seemed to be of too short duration for complete control of the

tumours. Some fractionation of the dose was therefore indicated and it was found that the best method of fractionation was as follows: 1,000 r – – 500 r, 500 r – – 500 r, 500 r – – 500 r – –, 250 r – – 250 r (– – represent two days on which no treatment was given). The total dose of 4,000 r was thus spread over eighteen days. The result of an experiment with this fractionated dosage is shown in Fig. 3 (*from* Elson and Lamerton, 1949). The large initial dose (1,000 r) appears here to have such a strong inhibiting effect on the tumours that a marked difference is no longer observed between the initial response of low and high protein diet animals. The effect of the high protein diet on the process of tumour regression and on the ability of the animal to rid itself of the tumour now becomes the most important factor in deciding the response of the animal to treatment.

In this particular experiment all animals maintained on the 20% protein diet were cured compared with only one cure in those maintained on the 5% protein diet. From a number of experiments with this fractionation technique used on tumours of a similar size and growth rate, complete regressions have been obtained in nearly 90% of the animals maintained on the high protein diet, but in only about 15% of those maintained on the low protein diet.

These experiments suggest therefore that to secure the most favourable response of the Walker rat carcinoma to radiation a primary necessity is suitable fractionation of the dose. The subsequent behaviour of the tumour may then be determined to a very large extent by the nature of the diet of the animal.

In considering this dietary effect one must separate to some extent the processes which determine (*a*) the initial response of the tumour, and (*b*) the elimination of the inhibited tumour and cure of the animal. Process (*a*) is found to be favoured by a low protein diet and process (*b*) by a high protein diet.

By suitable fractionation of the dose, however, it is possible to apply direct to the tumour a first dose of radiation sufficiently high to bring about an adequate initial growth-inhibitory response even in animals maintained on a high protein diet, so that the subsequent outcome of the treatment then depends almost entirely on process (*b*) and a favourable result is thus to a very large extent dependent on a high protein content of the diet.

The question now arises of the nature of this effect of high protein diet and here a wide field of investigation is opened up, whether for instance a certain type of protein (casein has been the main dietary protein used so far) or any of its constituent amino-acids are particularly concerned and whether other nutritional or hormonal factors can contribute to the effectiveness of the treatment.

Investigations of this nature are therefore being carried out in which the weight and food intake of each animal are recorded daily together with the progress of the tumour.

Since the radiation treatment has an inhibiting effect on the growth of the whole animal

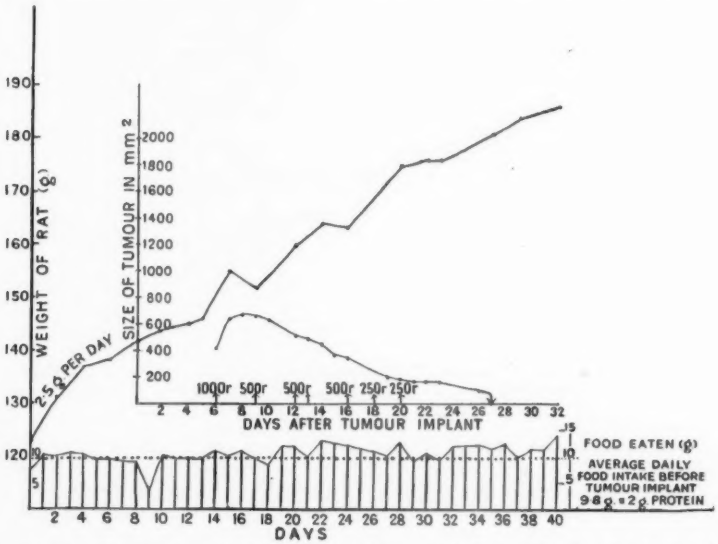

FIG. 4.—Growth of Walker Rat Carcinoma 256, weight, and daily food intake of animal maintained on a 20% protein diet and treated with X-radiation, fractionated doses, total 3,500 r.

as well as on the growth of the tumour, the end-result depends not only on the tumour-inhibiting action of the radiation but also to a considerable extent on the capacity of the animal to withstand deleterious effects. In some cases it appears possible that it may even depend in the first place on the ability of the animal to regain quickly or surpass its normal daily food intake after each treatment.

Thus in Fig. 4 the first (and largest) dose of radiation caused only a slight loss in weight of the animal and very slight diminution in food intake. The animal quickly recovered and thereafter during the whole of the period of radiation maintained an average daily food intake rather higher than its daily average before implantation of the tumour: this animal was cured. The rat represented in Fig. 5, however, showed a diminished food intake immediately follow-

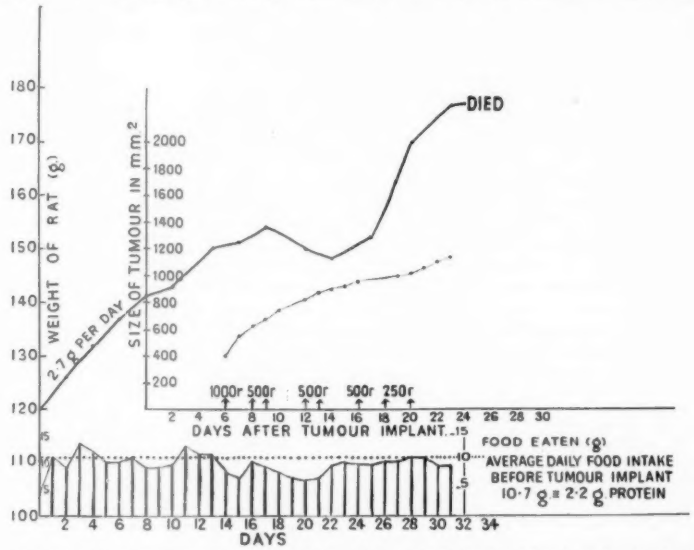

FIG. 5.—Growth of Walker Rat Carcinoma 256, weight and daily food intake of animal maintained on a 20% protein diet and treated with X-radiation, fractionated doses, total 4,000 r.

ing the first radiation treatment and during the whole period of treatment never regained the daily food intake of 10·7 grammes which was its average in the period before tumour implantation. This animal was not cured by the radiation treatment.

Such results suggest the possibility that some sort of protein efficiency index may be developed which may act as a guide to the probable reaction of the animal to the therapeutic agent. A more rational approach to the problem of cancer therapy is thus envisaged in which the growth-inhibitory action of the therapeutic agent is applied so that its maximum effects can be directed to the tumour itself, and deleterious effects on the animal minimized by suitable dietary or other means.

Dr. Benjamin Jolles (Northampton): An enhancement of the effectiveness of the radiation administered to a tumour can be achieved by fully utilizing the indirect effects of radiation, and by allowing to develop in the appropriate manner and time, processes in the irradiated and adjacent neighbouring tissues which lead to the destruction of a tumour and contribute to the recovery and repair of the damaged parts.

In a new method (Jolles, 1949*a*) of treatment of accessible tumours which is a complete

departure from all the existing methods in use, in both fundamentals and technical details, portions of the tumour 1 cm. square are exposed to radiation while other portions of similar area are protected so that important structures remain undamaged and can contribute to repair. After a suitable period of treatment another chessboard sieve, in which the order of opaque and transparent areas is reversed, is used, and the previously untreated areas are exposed while the already treated areas are protected and their recovery not hindered.

The time factor, which in the conventional radiotherapeutic methods is related to the cell life-cycle and to the attainment of the highest tolerable dose with the avoidance of damage to the skin, in the alternating chessboard method assumes a new complexion. It is to the recovery period of connective-tissue fibres, fibroblasts, &c., that prime consideration in the distribution of the dose of radiation is given.

The sieve method permits the histological study of the various reactions taking place in normal and malignant tissues, and the study of the relative importance of these various reactions in the radiation response of tumours.

In a series of experiments carried out on volunteers, a dose of X-rays was given to two small areas of skin separated by varying widths of untreated protected skin, and the reactions produced were significantly bigger than that over a single area of skin exposed to the same dose of radiation. When, however, the separation between the two paired areas was greater than a certain minimum value, the reaction was equal to that of a single area at a symmetrical site. The separation value which cancelled this reciprocal vicinity effect was, for areas 1·56 cm. by 1·56 cm., approximately 2·5 cm. For areas 2·5 cm. by 2·5 cm. a separation of at least 3 cm., and for areas 3·5 cm. by 3·5 cm. a separation of more than 4 cm. was required to abolish the vicinity effect (Jolles, 1949*b*, 1950) (4 slides shown).

It was previously stated (Jolles, 1941) that, the dose per unit area remaining unchanged, the reaction becomes a minimum when the normal tissues can exert their maximum protective role. In practice, this has proved to be the case in both X-ray and interstitial radium therapy. Introducing the perimeter/area and the shell area/volume ratios, a more comprehensive set of data are at hand when assessing the tolerable and optimal effective doses (Jolles, 1946, 1947, 1948).

The reciprocal vicinity effect of irradiated tissues is brought about by a complex mechanism in which, among others, a diffusible substance produced in the directly irradiated parts might play a role. It is tentatively suggested that apart from the reactivity of the surrounding not irradiated tissues this diffusible substance might be responsible for the events taking place in the parts of tumour shielded from the direct beam.

The hypothesis of a diffusible substance would lead not only to the expectation of the reaction produced by a given dose being less when the area to which it was administered was less, but also to the expectation that a given dose given in a short time would produce a greater effect than the same dose given to an equal area but spread over a longer time by fractionation or by reduction of intensity. For when the radiation is administered slowly the diffusible substance would diffuse away from the irradiated area too rapidly for the necessary concentration for the skin reaction to be achieved.

Dr. P. C. Koller: The experiments of Dr. Elson demonstrate the importance of tumour-environment in the radiation reaction of the Walker carcinoma. It has been shown that the sensitivity to X-rays can be influenced by diet. While the sensitivity of tumour-cells as measured by the chromosome injuries is the same in animals kept on different diets, the radiation reaction of the connective tissue capsule is more favourable on high than on low protein diet. The histological organization of the connective tissue capsule around the implanted tumour differs on the two diets. It seems that the histological structure and degree of radiation response of the tumour-bed are closely related, and that in the destruction of tumours its role is very important. We have more evidence in hand to show that the reaction of tumour environment to radiation can be influenced by physical and chemical means. The chessboard method of Dr. Jolles, by which the radiation dose is fractionated in time and space and the employment of synkavit by Professor Mitchell demonstrate the practicability of applying this fundamental principle in the treatment of human carcinomata.

Dr. L. F. Lamerton, in reply to a question on the epilation dose, said that the hair of the rats had in fact grown after a total dose of 4,000 r.

JOINT MEETING WITH THE BRITISH INSTITUTE OF RADIOLOGY

The Intensification of the Fluorescent Image in Radiology

By F. I. G. RAWLINS, M.Sc., F.R.S.E., F.Inst.P.

The National Gallery, London

THE method of observing the shadow-pattern cast by a beam of X-rays upon a fluorescent screen, when they pass through an object is well known in medical practice, in industry, and in the fine arts. In all these fields its diagnostic value is considerable, but in the first of them the possibility of excessive dosage is a risk to be taken seriously, and in any case the long period of visual adaptation in the dark is a practical drawback for the observer. So far as industry and the fine arts are concerned, this latter disadvantage remains, with the additional one—not so likely to occur in medicine—that not infrequently it is necessary to examine the object itself in daylight during the course of the fluoroscopic tests, and hence the pre-adaptation is vitiated. Inanimate objects of course need either manual or mechanical moving, or else the apparatus itself must be mobile, which adds to the general complexity. Various schemes have been proposed to achieve these ends, none of them wholly satisfactory.

Thus, there is a real urge to strive for some degree of intensification of the fluorescent image, bearing all these factors in mind. The human eye, though we cannot alter it, is capable of receiving information (and conveying it to the brain) to an extent scarcely realized a generation or so ago, given appropriate physical means.

Mathematical analysis shows that greatly increased brightness can be obtained by optical devices alone if we are concerned with a point-source, or at least extremely limited areas. But this is not so for the case of an "extended scene," that is, when we wish (as we do) to examine a surface comprising say 20 square inches, or something of that order. Then, energy must be brought into the system from outside and this is, in fact, what is done with "brightness intensifiers", two of which will shortly be described. Whatever optical arrangement is used as part of the apparatus, depth of focus will inevitably be lost. Should it be desired to couple a television pick-up tube for remote viewing, or even for further brightness-intensification, the signal-to-noise ratio, important in any case, becomes of greater significance. An effect is to be expected not unlike that experienced in observing at close range an over-enlarged half-tone photograph. Under these conditions, the coarse dot-structure makes the picture almost unintelligible, but across the room this is not so. Actually, as the illumination level is raised, the confusion increases slowly, and therefore the beholder's comfort can be met by providing rather more brightness than is theoretically justified. Furthermore it seems that the human eye possesses the remarkable faculty of "pooling" rod-vision and cone-vision over a fair range of excitation, so that we are not restricted rigidly to the use of rods only or cones only. Also, what has been termed a "variable gain" arrangement permits the build-up of the "message" by successive multiplication rather than by large sudden jumps.

The properties of fluorescent screens may now be reviewed in so far as they influence the main problems. They convert into visible light something like 30% of the X-ray energy which they absorb. Unluckily they only absorb some 15% and therefore the final efficiency is around 3 or 4%, allowing for losses. From this it follows that a "perfect" screen could only enhance the brightness level some thirty-three times or so, whereas, to be of any practical value, we are seeking a step-up of several hundredfold. This demonstrates clearly the magnitude of the effect for which we are looking. Furthermore, examination of a radiograph is commonly conducted at a brightness level of around 30 millilamberts whereas fluoroscopic work is carried out at an illumination of between 0·0001 and 0·001 millilambert, compared with the threshold for photopic vision of about 0·01 millilambert. At such low figures, the eye's discrimination for fine detail (line and contrast) is much enfeebled, which adds yet another reason for amplication of the fluorescent image in practice. It should perhaps be borne in mind that the long period of dark-adaptation needed at present adds very perceptibly to the responsibility of the observer, to make sure that he is, in fact, fully conditioned before beginning an examination at such low brightness levels as may easily be encountered in unfavourable cases.

Intensification Apparatus

An electronic tube, due to Dr. Coltman (1948) of the Westinghouse Corporation U.S.A., consists of a series of phosphors by means of which light is converted into electrons, which are accelerated by the application of a suitable high potential, and impinge upon another phosphor for re-conversion into visible light. The focusing is by means of electrostatic lenses, similar in principle to those used in the electron microscope. The initial brightness-gain of some twenty times is increased by a special optical system by a factor of twenty-five making a total step-up of 500-fold. As at present designed, this tube is 15 inches long, and 7·5 inches in diameter, and the field of view is a circle 5 inches in diameter.

A different device, constructed at Chicago for Dr. Moon (1948), comprises a scanning tube, the X-ray beam passing through a minute pinhole on to a specially constructed fluorescent surface situated in a spherical " collector." A photo-electric current is generated, amplified, and brought to a kinescope in such a way that by the use of synchronous currents a shadow-image is produced. More than one kinescope can evidently be used if desired.

In general, it should be remembered that the observer will need to position himself axially with respect to the tubes in the former case, and that in the latter the use of X-ray units of very high power is implied. These considerations introduce problems of a practical kind into which it is inappropriate to enter here : enough has perhaps been said to show the potentialities of amplification of the fluorescent image in radiology.

This paper will be published *in extenso* in the *British Journal of Radiology*.

Section of Orthopædics

President—NORMAN CAPENER, F.R.C.S.

[*November* 1, 1949 *contd.*]

? Cavernous Angiomata.—V. M. FRANKLIN, F.R.C.S.Ed.

Patient, a school teacher, aged 32.

First seen in June 1948 complaining of pain in her back which she dated to the birth of her baby 17 months previously. She had been under the care of a gynæcologist and general surgeon who, during investigations, discovered a tumour formation of the third and fourth lumbar transverse processes—the tumour also involved the body of the third lumbar (Fig. 1).

FIG. 1.—Showing collapsed body of third lumbar vertebra with tumour formation of third and fourth left transverse process and the right ala of sacrum.

At this stage the patient was referred to the Orthopædic Department. Further X-rays showed that the right ala of the sacrum was also involved.

The tentative differential diagnosis was then: (1) Multiple cavernous angiomata; (2) Giant-cell tumour; (3) Multiple myeloma.

Investigations.—Blood count normal. Bence-Jones protein negative on repeated examinations. Sternal puncture normal. Acid serum phosphatase normal. X-ray of other bones of the skeleton negative except for a questionable small defect in the parietal region.

Treatment.—Deep X-ray and corset.

I am showing this case first to ascertain whether my provisional diagnosis of cavernous angiomata is correct, and secondly as to whether any other treatment can be suggested. She is a young, healthy woman, putting on weight; in her corset she is completely free of pain and is unwilling to have an operation unless it is essential. She wishes to have another child but I have advised against this. Brailsford mentions 9 cases in the literature of cavernous angiomata of the spine, of which 7 have died from compression of the cord.

POSTSCRIPT.—When seen in April, 1950, the patient was still perfectly fit.—V. M. F.

A member from Edinburgh said that he had recently seen a case with similar X-rays which proved to be a myelomatosis, and other members suggested a diagnosis of myelomatosis in the present case.

The President said that against the diagnosis of myelomatosis was the age of the patient, 32, but he had recently had to operate upon a young man aged 26 who had a tumour of the twelfth dorsal vertebra with paraplegic symptoms and the lesion resembled a cavernous angioma. Microscopy, however, showed a plasmacytoma.

In the present case the absence of Bence-Jones proteose did not negative the diagnosis, because in 30% of the cases of plasmacytomatosis it was absent. Moreover it was more commonly found in the later rather than in the earlier stages. Perhaps Mr. Franklin would report the case again to the Section later.

[*December* 6, 1949]

Stenosis of Carpal Tunnel, Compression of Median Nerve and Flexor Tendon Sheaths, Combined with Rheumatoid Arthritis Elsewhere.—L. S. MICHAELIS, M.D.

The patient to be described provided an opportunity of studying the surgical and pathological problems set by this rare condition and offered clues for the answers to four questions: (1) The cause of compression; (2) its pathogenesis; (3) its site; (4) the cause of "weakness" of flexion and extension of the fingers, mentioned but not explained before.

Miss G., now 59, a former dancer and dancing teacher with well-developed muscles, did strenuous manual work during the war, particularly in an aeroplane factory early in 1944.

Part of her work consisted in stretching stiff canvas material tightly over frames. This she did mainly with her right hand, the left meanwhile steadying the frame.

Within a few months she suffered from attacks of intense pain shooting from her right palm into the tips of her fingers. The pain subsided intermittently but returned after renewed effort. Since the end of the war all light manual work, e.g. knitting, led to numbness and "pins and needles" in palm and medial fingers.

In 1944, also, the fingers of her left hand swelled, several joints becoming and remaining thickened and showing temporary stiffness but no ulnar deviation.

In 1948 both shoulder-joints became temporarily painful and stiff. The left joint recovered soon, but the right swelled to double its size and remained permanently enlarged and tense. Movement was limited, pain not severe.

In the last six months movements of the fingers of the right hand became more and more difficult, without any visible changes in the fingers. The flexor tendons appeared to be caught at the wrist. The ulnar two fingers in particular were found, on waking up, to be either maximally flexed or extended. And it took the patient a long time and much pain in the palm to straighten or bend them. In the effort of trying to do so, "lumps" appeared above and below the carpal ligament and there was here a crunching feel and noise on movement. Within the last few months a hard small swelling formed over the flexor aspect of the distal joint of the right thumb. It was tender to touch and interfered with her ability to grip.

The patient was highly strung, very apprehensive and depressed, under treatment for high blood-pressure and "nerves" for a long time.

On examination the lesions already described were found. No other joints were involved, the general condition was good, the B.S.R. 11 mm. in first hour, 25 mm. in second hour. X-rays showed no bony changes in the right shoulder, the cervical spine or either hand.

The sensory disturbance in the median distribution was severe but its outline was blurred. There was no motor paralysis but slight paresis and wasting of the thenar muscles on the right. On the left there were no neurological signs or symptoms.

Diagnosis.—Rheumatoid arthritis—in a silent stage—of left fingers and right shoulder. Stenosis of carpal tunnel with compression of median nerve and flexor tendon sheaths right.

It was decided to (1) split the transverse carpal ligament, (2) remove the hard body on the thumb, (3) open and wash out the right shoulder-joint.

Operation (L. S. M.).—General anæsthetic.

(1) Bunnell incision over the right palm (*see* Fig. 1). The distal end of the tendon of m. palmaris longus and the proximal half of the palmar fascia were exposed and the tendon transversely divided. The inner—or dorsal—surface of the palmar fascia showed the strands of the normal insertion of the palmaris longus at the superficial surface of the transverse carpal ligament, spreading out fan-wise over its distal half to its distal margin.

The median nerve, proximal to the proximal margin of the carpal ligament, was found to be over twice its normal width and resembled a tendon in being yellowish and glistening with œdema of its sheath.

Under vision throughout the carpal tunnel was opened in the mid-line. The cut surface of the carpal ligament showed the following changes: From the proximal edge to half-way distally the ligament was about 1 to 2 mm. thick, elastic and of normal appearance. Its distal half, corresponding to the extent of the palmaris longus insertion, was thickened to 4 mm., rigid, and the cut surface stippled with whitish-yellow spots. These spots closely resembled, in miniature, the necrotic foci seen in the diseased tendon of the supraspinatus.

Within the distal half of the carpal tunnel the median nerve was diminished in size, assuming further distally its normal thickness. The tendon sheaths of the flexor tendons were not thickened but, distally to the distal edge of the ligament, filled with clear watery fluid.

When the ligament had been completely split, extension and flexion of all fingers were free. The fluid in the tendon sheaths now flowed back proximally. The skin was sutured.

(2) From a Bunnell angle incision (*see* Fig. 1) the hard body over the flexor surface of the end joint of the thumb was removed. It had what at first appeared to be a thin capsule from which it was easily released. The joint was not opened.

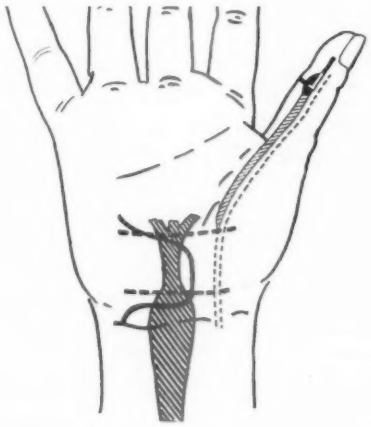

FIG. 1.—The two incisions used:—(1) in the palm; (2) over the distal flexor crease of the thumb.

See also:—
Position of carpal ligament; compressed median nerve; effusion and loose body in sheath of flex. poll. lg.

(3) From a 2 inch incision 1 in. lateral to the delto-pectoral groove the capsule of the right shoulder-joint was found to be tense and bulging with fluid content. On opening the joint about 60 c.c. of straw-coloured fluid escaped, containing many fibrinous flakes. The synovial membrane was much thickened, dark red, and further fibrinous material could be removed from its surface by washing out (1 eusol in 10 saline). The opening of the capsule in the upper part of the front of the joint was intentionally not sutured to allow drainage of the reactive effusion into the soft parts—a valuable procedure. Muscle and skin were sutured.

The patient made a smooth recovery, the freedom of movement of the fingers and absence of pain being noticed at once. On removal of stitches on the eighth day all wounds had healed. There had been, during the first few days, leakage of effusion-fluid from the lower angle of the shoulder scar and—this was not at first properly understood—from the thumb incision.

Pathological investigation of the fluid from the shoulder-joint showed it to be sterile.

The hard body from the thumb was sausage-shaped and over 1 cm. long. It had a firm smooth surface. The pathologist, finding many giant cells in a collagen stroma, called it a giant-cell synovioma (*see below*).

Discussion.—Our patient has several points in common with those mentioned in the literature:

A middle-aged woman, hard manual work to which she was not accustomed, signs of compression of the median nerve cured by splitting the transverse carpal ligament. With Russell Brain's and two of Newman's cases she shares the absence of bony changes which might have explained compression by exostosis encroaching on the tunnel-floor (Fig. 2A).

The lesion was one-sided, as in Woltman's and Zachary's second cases, in contrast to all others. The special manual strain fell on her right hand only.

Our patient differs from all those previously reported by showing this condition to be part of or coinciding with rheumatoid arthritis elsewhere.

She also had symptoms and signs of involvement of the flexor tendon sheaths which, if it was present in earlier cases, was not described or used to explain the "weakness" of finger-movement. The hard body from the thumb will be found to be part of this aspect of the condition.

Incision and approach to the transverse carpal ligament (Fig. 1).—The centre two-fifths of Bunnell's extensile incision for the palm of the hand permit wide exposure without causing a painful scar or keloid. (Bunnell, S., *J. Bone Jt. Surg.*, 1932, **14**, 27, *see also* Michaelis, L. S. Atlas Orthop. Operations, London, p. 32, Fig. 27C).

There is no valid reason to confine oneself to a remote approach from the lower end of the forearm. Any incision ending at the distal crease of the wrist prevents anything but blind splitting of the ligament in its distal half which, as we hope to show, means that the surgeon is bound to miss the crucial feature of the pathology.

Operative findings.—Anatomy: The operation afforded an opportunity to see how the insertion of m. palmaris longus grips the distal half of the carpal ligament. Contraction of this muscle pulls this part of the ligament palmarwards and removes the distal edge from nerve and tendon sheaths. At the same time the roof of the carpal tunnel is stiffened, is more resistant to pressure and better fulfilling its duty as a protector of the nerve. Part of the insertion of m. flexor carpi ulnaris lifts in the same manner the ulnar half of the proximal part of the carpal ligament (Fig. 2B, 3, 4).

This action, particularly of the palmaris longus, appears to have been overlooked so far. Besides tightening the palmar fascia and to a negligible extent helping to flex the wrist, the muscle is a tensor and levator lig. carpi transversi.

Where, as is common, the muscle is absent, the ligament cannot be tensed. But neither can the pathological condition be produced which is responsible for compression. There is no need to abandon the practice of using its convenient tendon for plastic operations.

When the palmaris longus muscle and tendon are taut, the distal mouth of the tunnel is opened. It appears that the position of wrist and fingers needed to make the tendon stand out differs slightly in different people according to minor anatomical variations. In my own wrists the tendon is most prominent (1) with wrist and fingers strongly flexed, (2) with wrist flexed 20 degrees and fingers hyperextended (Fig. 4).

In any other position of either wrist or fingers the tendon is either less taut or fully relaxed, e.g. if the wrist is sharply flexed but the fingers straightened, the tendon relaxes.

Maximal flexion of wrist and fingers at once appears to throw the greatest strain on the muscle. This is a position used when we pull and tightly grip, as in the present case, a canvas-sheet. This position also is often reached in washing and wringing laundry.

The significance of these facts for the pathology of carpal stenosis will become evident in the next paragraph.

Operative findings.—Pathology: (1) *Changes in the carpal ligament.* We have seen that its proximal half showed a normal appearance. The distal half, however, was greatly thickened, rigid and, on the cut surface, beset with necrotic foci (Fig. 2B).

These foci not only suggest comparison with those seen in the diseased insertion of the supraspinatus tendon; they are the same condition in a much smaller structure, brought about by the same agent, continuous and forcible muscle-pull on a tendinous sheet. In both cases fibrous tissue in the middle-aged, showing signs of beginning vascular changes, is affected in the same manner.

Certainly in our case, very probably in all cases where stenosis has not been caused by bony changes in the walls or floor of the tunnel, the cause of compression of the median nerve is to be found in the changes in the carpal ligament whose distal half was thickened, rigid and showed multiple necroses.

(2) *Changes in the tendon sheaths.*—The presence of effusion in the flexor tendon sheaths distal to the distal margin of the carpal ligament shows that stenosis is not confined to the proximal edge of the ligament but actually most pronounced at the distal edge.

Effusion was most noticeable in the sheath of flex. poll. long. which lies close to the radial bony wall and in the superficial plane, together with the nerve and the flexor sublimis tendons. The connexion between this effusion and the hard body removed from the distal flexor crease of the thumb occurred to me only at the end of the operation when watery fluid escaped from the angle incision. It now became clear that what had been assumed to be a "capsule" of the "tumour" was in fact the distal tip of the tendon sheath which had been pushed beyond the flexor-crease by the tense effusion (Fig. 1). The "tumour" was a loose body of the tendon sheath consisting of a concretion of synovial deposit. On the ulnar side, too, the superficial tendons of the fourth and fifth fingers, compressed between the bony wall and the now rigid roof, had been more affected than the central and deep tendons. This explains the selective limitation of movement of the ulnar fingers.

Conclusions.—In a middle-aged woman, suffering from rheumatoid arthritis of the left fingers and right shoulder, carpal stenosis and compression of the median nerve on the right were caused by thickening and rigidity of the transverse carpal ligament (distal half). This in turn was due to occupational overstrain on m. palmaris longus which normally lifts and tenses that part of the ligament. The flexor tendon sheaths, particularly of the flexor pollicis longus, were occluded at the distal edge of the carpal ligament. And a loose body had formed from deposits over the distal joint of the thumb.

FIG. 2A.—Carpal tunnel. Palm up.

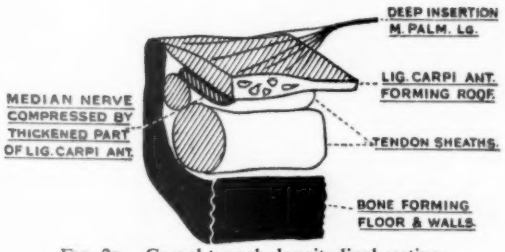

FIG. 2B.—Carpal tunnel: longitudinal section.

FIG. 3.—M. Palm. Lg.: deep insertion into distal half of Lig. Carpi Ant.
(*Superficial insertion into carpal fascia not shown.*)

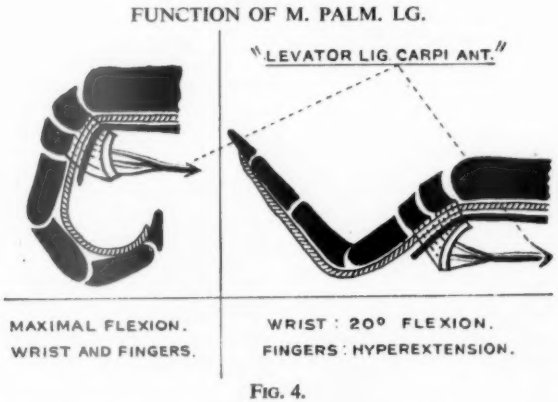

FIG. 4.

These changes in the roof of the tunnel explain compression in the absence of changes in its walls or floor which could be held responsible for the stenosis. "Increase in pressure within the tunnel" may well have been due to changes in the roof as here described. They could not have been seen as long as a remote approach was used. For future cases, free exposure by Bunnell's incision is recommended.

Arthrography of the Shoulder-Joint.—A. W. LIPMANN KESSEL, *M.B.E., M.C.*, F.R.C.S.

Introduction.—A study of the gleno-humeral joint by contrast-medium arthrography was carried out at St. Mary's Hospital, London, during the past two years because it had become apparent that some new technique of investigation must be developed if we are to advance our understanding of some of the many common shoulder disabilities.

The principal object of the work was to standardize the technique of arthrography, to learn what are the normal features of an arthrogram and to see whether it has any value in the diagnosis of injuries to the musculo-tendinous cuff. We also hoped that the investigation might shed some light on the pathology of the so-called "frozen shoulder".

This short paper is based on 25 satisfactory examinations and is preliminary to a full report which will be given to the International Radiological Congress in 1950 by my colleague in this work, Dr. D. H. Nelson, who was responsible for all the radiology.

Literature.—The use of arthrography in the diagnosis of injuries to the shoulder was first suggested by Codman [1], who stated that he was unable to obtain any useful diagnostic results. Oberholzer [2, 3] in some unconvincing work, claimed to demonstrate the capsular lesion in dislocation of the shoulder. The method, however, has only been fully developed in Stockholm, first by Lindblom and Palmer [4, 5] and more recently by Oliver Axen [6]. They are very enthusiastic about its possibilities. At last year's autumn meeting of the British Orthopædic Association, Withers [7] mentioned the use of arthrography of the shoulder-joint. In view of the fact that his report published in a recent issue of the *Journal of Bone and Joint Surgery* is the only reference to the subject in British literature, I should like to consider it at some length: "In establishing the diagnosis" (between complete and incomplete ruptures of the supraspinatus), "there is a place for arthrography", he says and he claims to do this by injecting perabrodil into the subdeltoid bursa. "It can then be demonstrated in a few minutes whether or not there is a communication between the bursa and the joint cavity."

Our experience does not lend support to this view. Unlike Withers, I have found it quite impossible deliberately to inject the subdeltoid bursa unless it is distended by an effusion. Indeed we regard it as indicative of an effusion if a bursogram is accidentally obtained. Furthermore we do not think that the interpretation of the films is so simple that, as Withers says, "It can be demonstrated in a few minutes whether or not there is a communication between bursa and joint."

If Withers' criterion for the diagnosis of a ruptured supraspinatous tendon is accepted, many patients may be subjected to unnecessary exploration, because coincidental filling of bursa and joint is almost always due to faulty technique, and only rarely and under special circumstances due to rupture of the musculo-tendinous cuff.

Technique.—The needle is introduced under local anæsthesia from a point 1 in. anterior to the acromio-clavicular joint, until its point is embedded in the articular cartilage of the head of the humerus. It is then slightly withdrawn while pressure is maintained on the plunger of the syringe. It is very important to remember that at the site of injection there is no more than a capillary joint-space. An important technical factor is the choice of a suitable needle; almost without exception failures are due to the use of a needle which has too long a bevel. It is only too easy to inject dye into the joint, the bursa and related soft tissue planes at one and the same time. I have found a child's lumbar puncture needle to be the most suitable.

At present we use 8–10 c.c. of 35% pyelosil. We discontinued the use of oily solutions because of some unpleasant reactions; our experience of air-arthrography is too small to give an opinion.

We followed Lindblom's advice on radiography which calls for some complicated positioning and at least 6 different views, but it is probable that one can get all the required information from two views: the first taken immediately after the injection while the patient is lying supine with the needle still in situ, and the second a good joint-space view taken at right-angles to the plane of the scapulo-humeral joint.

It is essential to do the injection under screen control if one is to be certain of the subsequent interpretation of the films.

The normal arthrogram is shown in the line drawing (Fig. 1) and radiograph (Fig. 2).

FIGS. 1 and 2.—The normal arthrogram.

[I]. A thin superior meniscus which outlines the articular cartilage on the upper half of the humeral head. Its precise limitation at the anatomical neck of the humerus indicates integrity of the musculo-tendinous cuff.

[II]. Delineation of the synovial sheath of the tendon of the long head of biceps.

[III]. Well-marked filling of the subscapular bursa.

[IV]. A pool of dye in the inferior joint recess.

Arthrograms of abnormal joints are shown in Figs. 3–7.

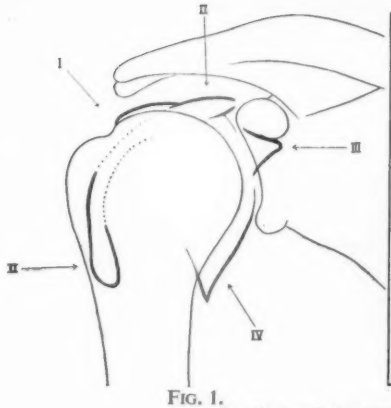

FIG. 1.

FIG. 2.

The Normal Arthrogram (Figs. 1 and 2).

FIG. 3.—Subacromial bursogram in a case of traumatic bursitis.

FIG. 4.—"Frozen shoulder"; note the obliteration of the inferior joint recess.

FIG. 5.—Rupture of supraspinatous tendon. The meniscus extends beyond the confines of the joint.

FIG. 6.—Rupture of supraspinatous tendon. Serial X-rays show progressive leak from joint into bursa.

FIG. 7.—Osteochondromatosis of shoulder-joint. Case shown to Orthopædic Section by Addison, J., on October 4, 1949 (*Proc. R. Soc. Med.*, 1950, **43**, 112).

Evaluation of the method.—I have not shown any examples of acute or recurrent dislocation, or ruptured long head of biceps. There are numerous such examples in the European and Scandinavian literature—50 of Lindblom's original 107 investigations were on patients suffering from rupture of the long head of biceps, but I think this can only bring discredit on the technique because it laboriously establishes what is already known by clinical observation.

In the diagnosis of supraspinatus injuries, Lindblom states that: "The value of the clinical signs is limited and relative . . . but arthrography, if properly carried out, provides exhaustive information regarding the existence of the rupture, its type, site, &c."

From our experience we cannot, as yet, share his enthusiasm but I am sure arthrography has a useful place in selected cases.

We examined 3 patients who displayed the "frozen shoulder" syndrome, and in each we found a degree of obliteration of the inferior joint recess. (May this not be secondary to almost *any* lesion which causes a stiff adducted shoulder?) We found no evidence to support the view of Nevasier [8] who states that adhesions exist between the synovial membrane and the head of the humerus, or the idea put forward by Lippmann [9] that the underlying lesion in a "frozen shoulder" is bicipital tenosynovitis.

Conclusion.—Using 35% pyelosil, arthrography of the shoulder-joint is usually, but by no means always, painless if a completely intra-articular injection is made. There are, however, occasional unpleasant reactions and the routine use of the method must carry certain risks. We cannot at this stage recommend arthrography of the shoulder as a routine investigation—as it is used, for instance, in congenital dislocation of the hip-joint—but once the technique is standardized it should prove helpful.

During the course of this work it has naturally given rise to some ideas about disorders of the shoulder region. I should like to end with some general remarks which, although they do not arise directly from the subject of this paper, may be of some interest:

I think that many so-called supraspinatus disorders are really disorders of the acromio-clavicular joint.

It is probable that the cause of the "frozen shoulder" syndrome will often be found elsewhere than in the gleno-humeral joint.

And finally, I believe that the gleno-humeral joint is a singularly blameless structure, and is much maligned.

In conclusion I should like to thank Mr. V. H. Ellis without whose encouragement and helpful criticism this work would not have been carried out. I also thank Dr. Cardew of St. Mary's Hospital, Clinical Photographic Dept., for the preparation of the slides and photographs.

[*January* 4, 1950]

DISCUSSION ON TREATMENT OF ACHALASIA OF THE CARDIA

Mr. N. R. Barrett: Our topic is one about which there are important divergences of opinion and I shall be surprised if my observations meet favour. They are based upon a group of 40 patients who have attended my Out-patients Department for periods in excess of a year.

First let us agree to define the scope of our subject and to use the term " achalasia " which, in the present state of our ignorance, is synonymous with " cardiospasm". These words describe a clinical entity in which there is a prolonged subacute obstruction situated at the lower end of the œsophagus, but without an organic stricture. I submit that we are not discussing those states of temporary or transient spasm induced by emotions such as fear or excitement, or by demonstrable pathological lesions such as carcinoma of the stomach, peptic ulcer, cholecystitis, &c.

The differences between "primary achalasia" and these secondary conditions of spasm cannot always be diagnosed by the radiologist or even the endoscopist, for the shape of the column of barium which the former studies and the configuration of the lumen of the gullet which the endoscopist scrutinizes, are often identical in true "achalasia" and in spasm. But at operation the external appearances of the gullet are pathognomonic. Spasms, induced by pathological conditions, relax under anæsthesia; but in "primary achalasia" the findings are constant and typical: the point at which the œsophagus actually enters the stomach is normal (I hesitate to call this "the cardia" because by placing metal clips at the junction of the squamous and the columnar epithelium, Allison has demonstrated that what looks like "the cardia" through an œsophagoscope may be shown, upon subsequent fluoroscopy to be situated at some distance from the clips placed at the junction of the gullet and the stomach at thoracotomy). Immediately above the cardia there is a segment of gut, approximately 4 to 6 cm. in length, which is about the shape of my little finger. Apart from its compactness and its smallness, the narrow segment is, in all other respects, normal ; that is, there is no evidence of inflammation, no adhesions, no increase in vascularity and no constant abnormality *vis-à-vis* the nerve supply, the crura of the diaphragm or the liver tunnel. It is agreed that the first inkling of achalasia is often increased irritability of the whole gullet below the aortic arch, and that this is soon associated with subacute obstruction focused at the lower end. Which of these two is the cause and which is the effect is not settled; nor is it known what sets the ball rolling. Above the obstructing segment the changes in the walls of the œsophagus are comparable to those found in the colon in Hirschsprung's disease; but it is not wise to carry the analogy further at the moment because the pathological changes which are said (Bodian, M., Stephens, F. D., and Ward, B. C. H., *Lancet* 1950 (i), 19) to be a constant feature in the recto-sigmoid segment—namely, complete absence of ganglion cells from the intramural plexuses and the finding of numerous non-medullated nerve bundles with supporting cells in the customary sites of the intramural autonomic plexuses—have not been found by all authorities in achalasia: nor are the problems of treatment comparable.

The changes in the dilated part of the gullet are proportionate to the duration and the completeness of the obstruction, and however distorted and inflamed the upper œsophagus may become it is my experience that the lower constricting segment takes no part in these changes. One other observation is relevant to treatment, namely that despite severe clinical obstruction it is always possible to pass an instrument into the stomach provided only that the way can be found.

In suggesting that the discussion be limited to the treatment of "primary or idiopathic achalasia" I stress that, as achalasia and carcinoma occur in the same age groups (Fig. 1),

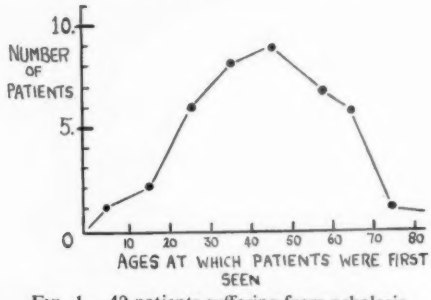

FIG. 1.—40 patients suffering from achalasia.
NOTE.—Many of these patients come within the carcinoma age period.

there will be occasions when only thoracotomy can settle the diagnosis; and as regards achalasia itself that there are often no clinical methods of gauging the existence or the progress of the disease. I have records of several patients who, upon their own statement, are in good health but in whom a barium swallow reveals distension and distortion of the œsophagus by residue held as high as the base of the neck.

Active treatment of any condition is based upon a knowledge of the outcome when nothing is done. In "achalasia" there are those whose disability is slight and who, by a variety of ingenious swallowing and dietetic tricks, and perhaps by the intermittent use of octyl nitrite, can so order their lives that nothing more is necessary. I advocate conservative measures at the extremes of life: in infants the behaviour of the cardia, both anatomically and physiologically, is to me so mysterious that any measure which will gain time—short of surgery—is to be recommended. It is my impression that the disease is more certainly self-limited and self-curative in children than in adults.

In adults the disease may not only have periods of clinical remission—during which the radiological abnormalities seem to persist unaltered—but the patients adjust themselves to a state of permanent sub-normal health and often cannot be persuaded to stake their claim for a chance of cure. They forget what it feels like to be really well.

Others are driven to seek help because the disease and the disabilities progress, and although death from starvation is unusual (because the liquid contents of the gullet are always dripping through into the stomach so that in time decomposing and offensive food becomes available for digestion) life can be rendered undesirable. When the patient has become "œsophagus conscious" and obstruction a permanent entity, the disease is then asocial as well as unpleasant. The victim cannot eat with, or even at the same speed, as others, cannot go out to entertainments, cannot take a holiday and finally does not dare to live.

This disease should be checked early and many believe that, at the outset, psychiatric treatment should be assayed. I take leave to condemn this practice because in my view it adds insult to injury. The treatment is based upon the widely held belief that achalasia is induced by some psychological upset, but for my part I cannot confirm this after careful review of my cases. Further I deny that any clinician can state—except in rare and exceptional circumstances—the moment when the changes in the œsophagus, which precede and account for the clinical manifestations, started. I have records of a ward sister who was at the peak of her active career, and who, during the war, went for a short holiday to a coastal resort. The Germans happened to bomb the place at that time and she received some minor injuries as a result of which chest X-rays were taken and a "large mediastinal hæmatoma" was considered to be present. In good health, but handicapped by a serious diagnosis, she was transferred post-haste to a thoracic surgical unit where it was ascertained that long-standing and advanced achalasia was present. It would be difficult to say when the changes in her œsophagus started. On the other hand I know that most people who develop achalasia have ample reason for becoming disturbed mentally, and that their troubles are speedily alleviated by curing the œsophageal obstruction: that is by placing the horse in front of the cart.

Another treatment, introduced in the seventeenth century, and resurrected in fairly recent times, is the mercury-loaded bougie; this is widely used. These instruments have served their purpose but are obsolete. There is no doubt that some patients not only get relief by regularly

passing a bougie but are happy to do so; for the majority, however, the instrument is repulsive to the patient and revolting to those lay people who find themselves watching the contortions it may necessitate before or during a meal. Moreover, the treatment is often ineffective either because the bougie curls up in the redundant pouch of œsophagus above the diaphragm, or because to achieve success the constricted segment must be stretched more than can be achieved by any instrument which the patient swallows. I damn bougies because they do not cure, because they induce a habit and a gamut of neuroses, and because they defer more effective treatment.

The quickest, the safest and the most certain treatment of the early case is by endoscopic dilatation of the narrowed segment; 60% to 80% of patients can be alleviated of all symptoms and cured in one or two treatments provided an instrument of the type devised by V. E. Negus be used. Success depends upon distending the œsophagus to such a point that the circular muscle fibres are ruptured—namely to a diameter of 5 to 7 cm.—and the surgeon who does this often enough will undoubtedly rupture the œsophagus one day. Rupture of the œsophagus can be corrected surgically, provided the early signs and symptoms are recognized and a diagnosis made. In another paper I have described these clinical features and have successfully diagnosed and treated this complication (Barrett, 1946 and 1947). My second point about endoscopic dilatation is that it is helpful to do the operation with X-ray screening facilities available: in this way the bag can be distended with radio-opaque liquid and the stretching observed and controlled under the eye.

I believe that patients who cannot be cured in this way should be advised to undergo operation without delay. To wait is to invite further deterioration, and as surgeons we are well aware that the chance of curing most diseases is inversely proportional to the time the patient has been afflicted. The majority of my patients suffering from "achalasia" have had dysphagia for five to fifteen years before they come to me.

A great range of different operations have been devised and tested during the last eighty years (Table I) and certain general principles can now be formulated. The failure or success

TABLE I.—OPERATIONS FOR ACHALASIA

Those Directed at the Baggy Œsophagus Itself

1 Excision of strips (Jaffe, 1897; Reisinger, 1907)
2 Œsophago-plication (Freeman; Meyer, 1911)
3 Œsophagostomia thoracica (Zaaijer, 1912)
4 Making the Œsophagus taut (Freeman, 1923)

Those Directed at the Narrow Segment

2 *Plastic Operations*
  A Cardiomyotomy (Heller, 1913; Röpke)
  B Cardioplasty
    1 Complete (Meyer, 1913)
    2 Extramucous (Marwedel, 1903) (Wendel, 1910)
3 *Excision*
  Cardiectomy (Rumpel, Pribam)
4 *Deviation*
  Œsophago-gastrostomy (Heyrovsky, 1912; Grondahl, 1916)

Those Directed at the Diaphragm

1 Phrenicectomy
2 Transposition
3 Division of the Crura (Brassler, 1914)

Those Directed at Nerves

1 Vagotomy (Meyer; Sauerbruch, 1921)
2 Sympathectomy (Knights, 1935)

[Modified from the Table in the Paper by A. Ochsner and DeBakey, *Archives of Surgery*, 1940. This paper contains a full list of references.]

of any operation can no longer be attributed to details of technique—for instance a plication of the redundant œsophagus does not fail because silk, as opposed to thread, stitches were used: nor need we discuss the relative merits of laparotomy as opposed to thoracotomy. Secondly, those procedures which have been directed at the obstructing segment itself have

been more efficacious than any others. Thirdly, although *any* operation which overcomes the œsophageal obstruction relieves all the symptoms and the reversible pathological lesions which afflict the patient, an operation which renders the cardia incompetent permits reflux of gastric contents into the lower œsophagus and causes "œsophagitis" in a high proportion of cases. The œsophagus, and especially the squamous epithelium which lines it, is extremely susceptible to gastric juice and is digested like the skin of the abdominal wall around a duodenal fistula. The exact mechanism which normally prevents regurgitation is not clear, since a muscular sphincter is not present, but the probability is that reflux is prevented because the œsophagus enters the side of the stomach obliquely, and this obliquity functions as a flap or valve. The valve effect is enhanced by the diaphragmatic pinch-cock, the fact that the œsophagus is surrounded on three sides by the liver (i.e. the liver tunnel) and by gas which is normally present in the fundus of the stomach. Whatever be the explanation it is certain that œsophago-gastrostomy, cardioplasty, excision of the lower constricted segment and other operations of this type are all apt to be followed by incompetence, reflux and "œsophagitis".

Up till 1947 I had performed 19 œsophago-gastrostomies (Table II). In all these patients the early results were brilliantly successful, and there was no operative mortality; but only 3 appear to me to be finally cured and I live in expectation that they too will develop symptoms one day. The remaining 16 have either had pain, dysphagia due to inflammation,

TABLE II.—ACHALASIA

Analysis of the results obtained in 40 *patients treated by me*

20 had been, or still are, being treated with *bougie*.
- 3 are good results.
- 17 continue bougie treatment or have ultimately been treated in other ways.

19 underwent *Œsophago-gastrostomy*.
- 3 good results.
- 16 imperfect results.

11 underwent *Heller's operation*.
- 10 good results.
- 1 imperfect result.

NOTE.—A "good result" is one in which the patient is symptomatically well at least one year after operation. An "imperfect result" means that the patient still has signs or symptoms of local or general type.

or anæmia due to slow bleeding from the œsophageal mucosa. In some the symptoms—and especially anæmia—have been crippling and persistent; in others disability has been present from time to time, but in all there are radiological or endoscopic changes in the lower gullet and this seems to me to be undesirable. I must remind you that these pathological changes are situated in precisely that reach of the œsophagus which, before operation, had a normal mucosa. The patients themselves would not all express their disapproval in such strong terms, for they are prepared to pay a high price for being able to swallow; but some have had to have other operations to correct the mistake, and one is dead as a result. Some manage to carry on by taking iron or liver injections ; and some by sleeping in the sitting position; some refuse further treatment although they have an anæmia with a hæmoglobin as low as 50%.

In conjunction with R. H. Franklin I have recently published these late results (*Brit. J. Surg.*, 1949, **37**, 194) and he added 6 patients upon whom he had performed a cardioplasty (i.e. an operation in which the cardia and the narrow segment were opened longitudinally and sewn up transversely). 3 of his 6 patients were symptomatically cured, but 4 of these 6 are known to have active "œsophagitis" at present.

You will ask why these serious late complications have not been reported by other surgeons, and I can only assume that the reason is that the patients have not been followed up for a sufficiently long time. In 1940 Ochsner and DeBakey collected 88 examples of œsophago-gastrostomy from the literature and they state that there were 5 deaths and 82 good results. In 1945 Clagett, Moersch and Fischer added some more good results but their patients were only watched for a few months. Kay, writing in 1948, said that "great relief" followed seventeen transpleural cardioplasties, but he does not tell us about his late results. Gill and Child (1948), on the other hand, admit that most of the patients who were followed for six months to two years continued to have untoward symptoms referable to swallowing.

I must stress that of the various inflammations which affect the œsophagus and which are called "œsophagitis" two different types are relevant to this disease. The first precedes any treatment and is due to stagnation of food and saliva above the obstruction; it resembles stercoral ulceration, seen elsewhere in the gut, and often causes persistent pyrexia—pyrexia

of this variety is an indication for early operation; it will disappear as soon as the obstruction has been relieved. The second is the probable late result of most operations upon the cardia and is due to regurgitation of acid-pepsin into the lower œsophagus.

In my opinion two, and possibly three, operations relieve the obstruction without setting the stage for "œsophagitis" but *only one* of these should be practised. The first is transgastric retrograde dilatation—a procedure which was carefully tried out by Sir James Walton in this country and is now regarded as obsolete because it carries a relatively high mortality and morbidity rate and because better results can be had by endoscopic dilatation with the Negus instrument. The second is extra-mucous or intra-mucous cardioplasty and for this procedure good results have been claimed but they do not tally with Franklin's experience which I have already mentioned and therefore I recommend that the operation be discarded. The third is Heller's (1913) œsophago-cardiomyotomy in which the obstruction is overcome by dividing the circular muscle fibres of the lower œsophagus. This leaves the cardia intact and anatomically in its normal position. If the circular fibres are properly and completely severed throughout the narrowed zone the clinical results of Heller's operation are excellent: my own experience is limited to 11 cases all of whom were cured except one very old woman who was much relieved, but whose disease was far advanced. The operation is not followed by regurgitation and this has been verified both by screening the patients in the Trendelenburg position and by showing that neither acid nor pepsin can be found in the gullet. Wulff (1949), who has had experience of this operation, concurs with these observations, and with the fact that occult blood is not found in the stools post-operatively.

Heller's operation is safe; it can be done in a few moments by thoracotomy and the patients should be able, and allowed, to swallow normally as soon as they return to the ward. No complicated after-treatment is necessary or desirable, but any operations performed upon the lower œsophagus are sometimes complicated by a small, late, serous, pleural effusion. In some patients the X-ray appearances are not as satisfactory as the clinical state, but the patients put on weight and are well satisfied.

There are no people more grateful than those whose dysphagia has been cured. Indeed, the results of a successful Heller's operation can be far reaching; it is not unusual for divorce proceedings to be settled out of court, for bags to be packed and the family to go away for a holiday, for father to put on weight and mother to become pregnant.

Mr. P. R. Allison: I have studied and treated 76 patients suffering from cardiospasm. Of these, 34 were male and 42 female. The onset of symptoms occurred most often between the ages of 30 and 40 years (28%). The next most common decade was 10–20 years (18%), and the third 40–50 years (15%). Owing to the long duration of symptoms in these patients the greatest number of them presented for treatment between the ages of 40 and 50. Quite a high percentage of patients, however, were between 50 and 70 years of age when they first came to hospital for attention.

Three patients were treated over fifteen years ago by gastrotomy and digital dilatation of the cardia. All were relieved of their symptoms. Another patient was treated by spinal anæsthetic and died a few hours afterwards from inhalation pneumonia. As well as this death there have been two other fatalities, one from gross starvation, and one from perforation of the œsophagus and mediastinitis. Neither of these 2 patients had any treatment and were moribund when they came to hospital. A uniform routine of treatment has been adopted in all the other patients. It has consisted of œsophageal wash-outs, followed by œsophagoscopy and dilatation of the cardia through the œsophagoscope by the Negus hydrostatic dilator. When this has not been enough to relieve symptoms, the process has been repeated at least once and sometimes three or four times. Where the œsophagus is greatly dilated it is most important to wash it out and aspirate it before œsophagoscopy, and indeed before any anæsthetic is administered, if inhalation pneumonia is to be avoided. Altogether the Negus hydrostatic dilator has been used in 59 patients, and of these it has been the only line of treatment in 46.

The result in these 46 patients is described as "successful"; the definition of this term will be discussed later. It was unsuccessful in 13. Of the 46 successful patients, 29 were cured by

one dilatation, 15 by two dilatations, 1 by three, and 1 by four. I believe that the success of any method of treatment of cardiospasm depends on rupture of the circular muscle fibres at the œsophago-gastric junction. If this is to be achieved with the Negus hydrostatic bag, it is important that the walls of the bag, when distended, should be parallel, or otherwise it will slip either upwards into the œsophagus or down into the stomach without actually rupturing the muscle fibres at the cardia. The shape of the bag, when distended, depends on the way in which the linen lining beneath the rubber covering is cut and stitched, and this is liable to some variation from time to time and with different manufactures. Some of the failures have no doubt been caused by badly-shaped bags slipping. The success or failure of treatment does not seem to depend very much on the length of time the patient has had symptoms. A patient may have had dysphagia for fifty years and may still be cured by a single application of the bag. One of the most important points about this form of treatment is that it is an out-patient procedure. That a patient who has had many years' dysphagia and regurgitation may be cured of his complaint after one attendance at the out-patient department is a striking tribute to the method. The only complication has been a perforation of

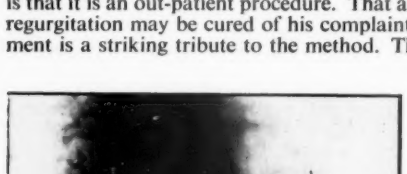

FIG. 1.—Cardiospasm with prolapse of cardia 2½ in. below the hiatus. Œsophagus a huge inert bag.

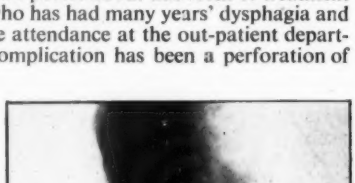

FIG. 2.—Same patient after Heller's operation combined with repair of diaphragmatic hiatus. Œsophagus greatly contracted, but still inert.

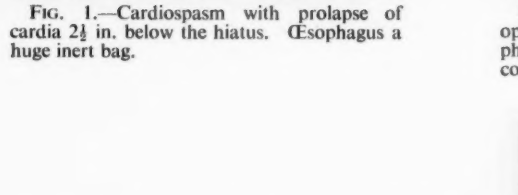

FIG. 3.—Extreme emaciation shortly before death. Starvation from cardiospasm.

FIG. 4.—Œsophagus and stomach removed post mortem from the same patient.

the œsophagus in the neck by the œsophagoscope. This was a complication of œsophagoscopy rather than of the Negus dilator, but it occurred in a patient with cardiospasm who was being treated under a local anæsthetic. Immediately the accident was recognized, the œsophagoscope was withdrawn and inserted into the œsophagus proper, the œsophagus was treated by aspiration and the cardia dilated, after which an incision was made in the neck and the tear sutured. The patient made an uninterrupted recovery.

The only other form of treatment which has been used has been the Heller operation. This consists in the division of the circular muscle fibres at the lower end of the œsophagus and adjacent part of the stomach. It can be done either from the abdomen or from the chest, but in this series the thoracic approach has been used entirely.

The Heller operation has been used in three groups of patients: firstly, for small children, where no great confidence has been felt in the ability to stretch the cardia without causing trouble; secondly, for those patients who have not been cured by the Negus hydrostatic bag; and thirdly, for those patients in whom the œsophagus has become so lengthened and tortuous that the cardia could not be reached either by the œsophagoscope or by the bag. In 2 patients, the inflammation at the lower end of the œsophagus with fibrosis of the œsophageal muscle was so marked that the mucosa was opened during the performance of the Heller operation, and had to be sutured. Of 19 patients treated in this way, the results have been classified as uniformly successful.

The approach to the cardia for Heller's operation has been through the bed of the ninth rib on the left side. After the pleura has been opened and the lung retracted, local anæsthetic is injected into the mediastinum, the mediastinal pleura is incised, and the finger passed round the lower end of the œsophagus. A tape is then passed round this for traction and the cardia is gently pulled up through the hiatus. The affected area is usually not more than $\frac{1}{2}$ in. to $\frac{3}{4}$ in. in length. It is cylindrical on section, and constricted. This area corresponds to that part of the œsophagus which normally lies in the diaphragmatic crural canal. Above it the œsophagus distends, and the wall is greatly thickened by hypertrophy of its muscle layers. A single vertical incision is made through the muscle tissue, starting about an inch above the cardia, and passing down across the cardia on to the stomach for $\frac{1}{8}$ in. to $\frac{1}{4}$ in. This incision is deepened down to the submucosa until the mucous membrane prolapses freely into the wound. The œsophagus is then allowed to retract between the diaphragmatic crura, the chest is closed and the lungs expanded. In one patient, where the hugely dilated œsophagus had prolapsed through the hiatus for about $2\frac{1}{2}$ in. into the abdomen (Fig. 1), it was felt that incision of the muscle in this way might render the lower end of the œsophagus, which was in the abdomen, liable to peptic digestion. In this patient, therefore, after division of the muscle, the cardia was drawn back between the crura, and the crural fibres were lightly stitched behind it (Fig. 2). There have been no patients whose symptoms have not been relieved by one or other of the above forms of treatment, and it has never been found necessary to have recourse to the more complicated operations, such as cardioplasty and œsophago-gastrostomy.

During the course of this discussion the word "successful" has been used in regard to treatment and it is, therefore, necessary to define as far as possible exactly what we mean by the word in this context. Success from the patient's point of view, of course, depends entirely on the relief of his clinical symptoms, but from the surgeon's point of view there are two aspects of this. Firstly, the clinical relief of symptoms, and secondly, the radiological changes. It is also necessary to emphasize that the word "success" must be taken to mean "success within the period of follow-up". Mr. Rock Carling has described a patient who was completely relieved of her symptoms for twenty years, but in whom dysphagia recurred suddenly when she found the lodger with his throat cut over the sink. I, myself, have had one patient who developed cardiospasm after the death of her mother, was completely relieved, and then developed it again on the death of her father. From the clinical point of view, a success is considered complete where a patient can eat normal meals without pain, without a sense of obstruction, without regurgitation, and without medicine. This includes patients who have to eat slowly and who (for reasons which will appear later) have to use fluids to clear the gullet. Success is partial where a patient eats normal diet, but has occasional feelings of obstruction. The gaining of weight and an increase of vigour are also important indications of clinical success. Sometimes a patient's only symptoms are pulmonary, either the result of inhalation of œsophageal contents, or collapse of a lung or lobe, due to pressure on a bronchus by a greatly distended œsophagus. In these patients the criterion of cure is that cough, pneumonic attacks, and pleuritic pains should be abolished.

In referring to the gain of weight on successful treatment, it is worthy of note that there are two main types of patients presenting with symptoms, firstly, the one who has lost a little weight in the beginning, but who subsequently maintains a steady weight and a steady food intake even though there is great retention in the œsophagus, and secondly, the patient who undergoes progressive starvation even to the point of death (Figs. 3 and 4). It is quite

unusual for patients with cardiospasm to be grossly undernourished, and the reason for this appears to be that the œsophagus retains all the food taken and allows it to pass through very slowly by continuous drip feed into the stomach.

The criteria of radiological cure are much more exacting, and it is comparatively rare to see the œsophagus return to normal anatomy and physiology after any form of treatment (Figs. 5 and 6). The degree to which success is demonstrated radiologically, however, unlike

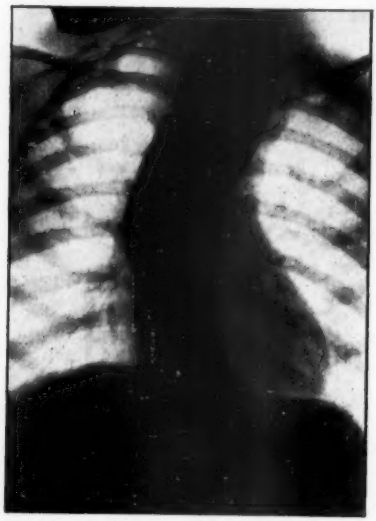

FIG. 5.—Cardiospasm in a child of 3 years. Symptoms since 4 months.

FIG. 6.—Same patient after left transpleural Heller's operation. Normal anatomy and physiology of œsophagus.

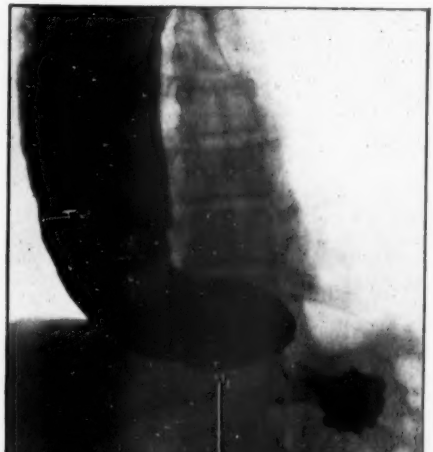

FIG. 7.—Advanced cardiospasm Stage 3 associated with rheumatoid arthritis, œsophagitis and pyrexia.

FIG. 8.—Same patient after Heller's operation. Clinically cured, radiologically imperfect. Some muscle activity present, but completely inco-ordinated. Passage of barium into stomach by gravity and respiration only.

clinical success, depends on the length of time the symptoms have been present, and the amount of dilatation of the œsophagus. Usually the radiological changes after treatment are in the reverse order to those occurring during the progress of the illness. It is, therefore, useful to comment on these. In the early stages of cardiospasm, a constriction with irregular muscle movements is seen in the lower two-thirds of the œsophagus with slight dilatation in the upper third. In the second stage the constriction is seen at the cardia, the lower two-thirds of the œsophagus begin to dilate, but movements, often inco-ordinated, are retained and even increased. In the third stage, constriction is limited to the cardia, and the rest of the œsophagus becomes dilated and passive. If the patient is treated in this last stage, the cardia may be dilated and food pass through the œsophagus by gravity and the force of swallowing, but active movements of the œsophagus are never regained. In such patients the picture of the œsophagus when filled with barium may look very similar before and after treatment (Figs. 7 and 8). In this way it happens that a patient may be completely relieved of his symptoms and be a clinical success, but the radiologist may give a disappointing report, especially if he is influenced by the amount of dilatation of the thoracic œsophagus. The treatment in the first and second stages, however, may result in very marked diminution in the size of the œsophagus, a much more co-ordinated activity, and an active passage of food from the œsophagus into the stomach in addition to that effected by gravity and respiration (Figs. 9 and 10).

FIG. 9.—Cardiospasm passing from Stage 2 to Stage 3.

FIG. 10.—Same patient after hydrostatic dilator.

No description of the treatment of cardiospasm would be complete without some reference to the side-lines of treatment. Chest complications have been found in 16% of the patients and have included bronchitis, pleurisy, paraffin pneumonia, bronchiectasis, lung abscess, and inhalation or pressure pneumonia. The treatment of chest complications is the treatment of the œsophageal lesion, for when this has been effected, the chest is likely to improve, except of course in the case of established bronchiectasis. Rheumatoid arthritis with clubbing of the fingers has been noted in 4% of the patients, and here again it is important not to be misled by the obvious deformities, but to concentrate on the treatment of the cause. In my experience drugs have given little or no benefit. Psychological factors in cardiospasm have frequently been stressed, but there has been very little evidence to suggest that psychiatric treatment has ever been effective in these patients. There is no doubt that most of the patients are "queer", but neither this, nor financial, family, or other worries seem to me to distinguish them in any way from their fellows. The best treatment that they can have, from a psychological point of view, is the relief of their dysphagia, so that they can eat at the family table, go out to restaurants, and mix freely with the rest of the world.

Mr. A. L. d'Abreu (*Birmingham*): Agreeing as I do with Mr. Allison about the ætiology of this condition, I find that although patients appear normal psychologically, the onset in most has followed acute emotional upsets. One patient, a first-class cricketer, suddenly developed symptoms during an important game and these persisted for twenty-three years until he was cured by a cardiomyotomy. Some patients have been extremely intelligent and others have appeared quite stupid; but some children have started their symptoms in the first months of life. In these very young patients progress, whether good or bad, depends largely on the intelligence of the parents and most of the infants maintain their nutrition well. The act of vomiting disturbs them little and I have seen them vomit a meal, but succeed a few minutes later in swallowing one of equal size and quality. Some children have had respiratory symptoms and my experience has been that of the opening speakers inasmuch as a surgical cure of the cardiospasm is invariably followed by improvements in chest condition. In particular, I remember one boy with long-standing cardiospasm who presented himself with radiological evidence of collapse of both lower lobes, which re-expanded after a satisfactory Heller's operation.

In the treatment of these patients I agree with Mr. Allison that the main duty at the first interview is to promise a cure. I dislike the use of Hurst's mercury bougie, and have never seen antispasmodic drugs give good results. If there is difficulty in curing the patients by forcible rupture of the muscle fibres by Negus's dilator, the modified Heller's operation should be proceeded with at once. In elderly patients (three of mine were over 70) it may be preferable to perform this operation without previous attempts at œsophagoscopic dilatation, as often they have an enormous œsophagus and the instrumentation is not easy.

In twelve operations of cardiomyotomy relief has been immediate and continued in all except one. This patient, aged 71, could not remember the onset of dysphagia. The œsophagus was enormously dilated with a large loop passing well into the right side of the thorax (Fig. 1). After division of hypertrophied muscle fibres in the lower portion of the œsophagus

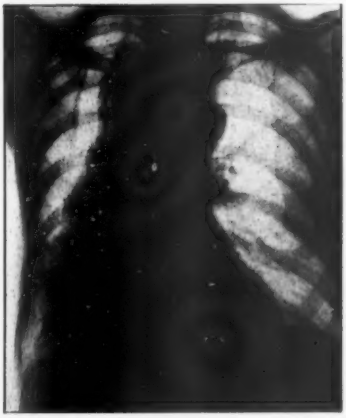

FIG. 1.—A straight X-ray of a grossly dilated œsophagus which extends well into the right thorax. Air can be seen above the clavicle and the sigma dilatation at the lower end reaches to the right cardiophrenic angle.

she was able to swallow anything and gained 1 stone in weight which has been maintained, but she still has occasional obstruction with regurgitation. The œsophagus has not regained its normal peristaltic waves, but possibly the extent of the myotomy was inadequate.

Sir Thomas Dunhill only wished to speak of two operations, and to pay a tribute to the work of the present generation of surgeons. Their spirit of enterprise and their practical achievements have kept pushing farther forward the contributions of surgery in the alleviation of suffering, and have based on secure foundations the treatment of conditions which an earlier generation approached tentatively and without sure knowledge.

Fig. 1 shows an œsophagus the result of cardiospasm which had prevented the patient from swallowing an adequate amount of food for thirty years. It had been treated in the early stages by means of a mercury bougie. The patient stated that this had never given her relief. The illustration shows the position of the bougie in relation to the "S"-shaped curve

FIG. 1.—Mrs. D. 1932.

FIG. 2A.—Mrs. J. 1.11.45.

FIG. 2B.—Mrs. J. After operation, 26.3.46.

of the œsophagus when I attempted gently to pass it. It also shows the impossibility of examining the cardia with an œsophagoscope in this patient. Subdiaphragmatic œsophagogastrostomy was performed in 1933. The patient lived for some years much more happily than before the operation, although the œsophagus did not empty. She died seven years later. She lived in the country and I could not get accurate information of the cause of death.

Two others were operated upon by this method. One reported for some years afterwards and then could not be traced.

Fig. 2A is from a patient upon whom I operated five years ago. She had been unable to swallow adequate nourishment for twenty years, and for a fortnight before operation had been unable to swallow at all. It was necessary to give transfusions for several days, and then a jejunostomy was performed. Following this, with a transthoracic approach, the lower end of the œsophagus was dissected free from the diaphragm at the hiatus. A longitudinal incision was made through the muscle coats of the œsophagus for 2 cm. and continued for a similar distance on to the stomach. Fig. 2B seems to indicate that the diameter of the œsophagus had approached its normal size. This is not so, but it shows that the barium swallow is not held up—it passes through without delay. The patient now eats whatever the family eats, she has gained five stones in weight and is very happy. This is without doubt the better operation.

Mr. E. D. D. Davis: I have the notes of 34 cases of achalasia. Most of them were treated by dilatation through the œsophagoscope. Recently I have had the opportunity of dissecting the normal œsophagus in the full term and other fœtuses. Longitudinal sections have been cut of an 8 and 20 weeks whole fœtus to show the form and relations of the œsophagus. These anatomical and clinical investigations have been carried out at the Ferens Institute of Otolaryngology of the Middlesex Hospital (Fig. 1). The fœtal sections show the deviation of the

FIG. 1.—One of a series of longitudinal sections of the full-length 8 weeks fœtus to illustrate the form and relations of the cardiac end of the œsophagus.

œsophagus to the left and the abdominal or diaphragmatic portion curves slightly from before, backwards and obliquely to form an arch over the aorta. The orifice of the cardiac end of the œsophagus as it enters and blends with the lesser curvature of the stomach is directed slightly backwards. The two domes of the diaphragm dip downwards in the form of a V to enclose the œsophagus and the diaphragm is bound by areolar tissue to the wall of the œsophagus. The left crus of the diaphragm in section is almost triangular and dips into the angle where the cardiac end of the œsophagus deviates to the left. This inward bulge of the left crus cannot be seen with the œsophagoscope. The right crus is flattened and the two crura form a groove or canal for the œsophagus. The caudate lobe of the liver is parallel to and in relation to lesser curvature of the stomach and extends as far as the orifice of the cardiac end of the œsophagus. It is difficult to see how enlargement of the caudate lobe of the liver can press on, or distort, the cardiac end of the œsophagus. Dissections of fresh post-mortem specimens of the cardiac end of the œsophagus show the longitudinal folds of the abdominal œsophagus to be much enlarged and thickened. It is apparent that the prominence of these folds reinforces the closure of the lumen of the œsophagus. The muscular wall does not show any sphincter but the circular muscular fibres are well developed and the

musculature becomes thicker as it blends with the wall of the stomach. The pale pink mucosa of the œsophagus ends abruptly as a clear line where it joins the thick velvety darker red mucosa of the stomach. The magnified sections show a clear line of demarcation between the mucosa of the œsophagus and that of the stomach. When the œsophagoscope passes the upper sphincter of the œsophagus air dilates the passage and the longitudinal folds are obliterated but the movement of the wall with deep respiration can be seen easily. The pulsation of the aorta can be felt and sometimes seen particularly near the cardiac end. At about 40 cm. from the teeth the stellate appearance of the hiatus of the œsophagus as it passes through the diaphragm is observed. Brown Kelly states that when the endoscopic tube is about 3 cm. from the hiatus the lumen rhythmically opens and closes with respiration. This movement is difficult to see and when the œsophagoscope passes through the hiatus the dark red mucosa of the stomach is immediately and abruptly seen. Sometimes regurgitation of gas and stomach contents are seen.

If a normal patient is observed with the X-ray screen swallowing barium cream, the barium cascades from the pharynx and slithers down the œsophagus and at the hiatus the stream of barium narrows. If the patient holds his breath following inspiration and when the diaphragm descends, the barium flow is stopped but it immediately passes into the stomach on expiration with the rising of the diaphragm.

When a patient suffering from achalasia is observed, the globular dilatation of the gullet fills with barium almost up to the thoracic inlet, then the weight of barium seems to force a trickle of barium into the stomach. Arthur Hurst stated that the mercury bougie should contain 1 lb. 5 oz. of mercury. Mosher found that a pressure of 3 lb. to 4 lb. exerted by his barium-striped dilatation bag was sufficient to dilate the cardiac end in achalasia. In one female patient ½ lb. pressure was sufficient. The movement of respiration is transmitted to the barium column, but no peristalsis was seen.

Dr. Campbell Golding of the Middlesex Hospital X-ray Department observed that the inhalation of octyl nitrite diminished appreciably the height of the column of barium necessary to cause a trickle of barium to flow into the stomach. Amyl nitrite upset patients to an alarming extent.

Brown Kelly stated that in achalasia patients when the tube of the œsophagoscope reached the hiatus the orifice closed firmly and relaxed when the tube was withdrawn to about 3 cm.

Dr. Wilhelmina Shaw Dunn divided both vagi nerves in cats, then fed them with barium milk. The X-ray showed a dilatation of the œsophagus without relaxation of the cardiac end. When the œsophagus was full of barium the cat vomited some of the barium. As expected, division of the vagus nerve in a few patients has aggravated the achalasia. Gilbert, Dey and Rall stimulated the vagi of cats and observed the contraction of the œsophagus with drawing upwards of the cardia through the hiatus. Hofer and Spiegel divided all the sympathetic nerve fibres to the œsophagus which could be found and observed that there was no change in the act of swallowing and that the sympathetic nerves were not antagonistic to the vagus. A patient who had had both stellate ganglia of the cervical sympathetic excised for vertigo was watched swallowing barium and no change in the act occurred.

There is sufficient evidence to assume that the cardiac end of the œsophagus remains closed at the hiatal level except during the passage of food. The cardiac end is closed by the contraction of the muscular tube reinforced by the action of the diaphragm similar to the closure of the larynx. The orifice of the larynx is closed by contraction of its muscles and it is then drawn up behind the base of the tongue.

The treatment of achalasia by dilatation through the œsophagoscope has been successful in early cases, when the hiatus is easily seen. The œsophagus should be washed out by large draughts of water or a weak solution of bicarbonate of soda morning and evening. At least half a pint of water should be taken after each meal. If a Hurst's mercury bougie is used the patient should be watched with the X-ray screen to see that the bougie enters the stomach.

The result of treatment is difficult to assess and patients may have no symptoms for long periods. For example 3 cases of achalasia were seen with complete dysphagia after swallowing a cherry stone, a plum stone and a large bolus of meat respectively. The fruit stones acted as ball valves and after removal the patients could swallow normally. The cardiac end was dilated but they did not return for treatment. The majority of cases of achalasia show a steady increase in the dilatation of the œsophagus seen by X-ray photographs in spite of treatment.

Mr. St. George B. Delisle Gray said he had listened with the greatest interest to these two excellent papers for he himself had suffered from achalasia of the cardia or cardiospasm since he was 29 years old. He is now 57. Personally he thought from his own sensations that it was a true spasm.

The first attack came on when he was drinking iced wine in Portugal. He felt the mouthful stick retrosternally, there was intense colic of the œsophagus for several seconds, the wine regurgitated into his mouth and then was swallowed quite naturally. He thought it was an œsophagual pouch, but was advised by Bizarro (a Portuguese surgeon with the F.R.C.S.Eng.) that it was a cardiospasm. On his return to England the condition got steadily worse; he could not drink hot or cold fluids and used to take everything lukewarm. He had to sleep well propped up as otherwise œsophageal contents trickled over into his trachea and he used to wake up coughing. Since the onset of the cardiospasm he has never vomited stomach contents except recently after dilatation. Several years ago he had an acute attack of pain, vomited up his breakfast and felt extremely ill. The condition was then confirmed by X-ray. He felt very much better after washing out his œsophagus with water. At times during the night he would wake up with acute retrosternal pain of a griping character. This was often relieved by leaning over the bed and emptying the œsophagus into the chamber. He noticed when he did this he brought up small solid chunks of food. If this did not relieve the pain he would get up and drink some water and this by dilating the œsophagus relieved the spasm; he would of course have to empty the œsophagus again.

In spite of this complaint he has lived a very active life and served throughout the War afloat on very active service. While in his ship at Sydney he had an acute attack of spasm. On his return to the U.K. Professor Grey Turner advised him to try a Hurst's Tube (No. 30) which he did, passing it three times a day for five minutes at a time. This greatly relieved his symptoms, and he put on 3 stone in weight in a very short time. For some time he has not been passing the tube as the one he has has become cracked and he did not relish the idea of the tube breaking and getting a stomach full of mercury. It is apparently impossible to get a new one. The condition has since got worse.

On swallowing food it can be felt to stick half-way down the œsophagus, and it is forced on by drinking copious draughts of water, which act similarly to flushing the W.C., when everything gets washed on. There is a sensation that the œsophagus is going to burst, suddenly the cardia relaxes and the food can be heard from the other side of the room passing into the stomach. It is important to drink *cold* water because the sensation of cold in the epigastrium when the cold water reaches the stomach indicates that all the food has passed through. Standing up makes swallowing easier. On passing the tube resistance is felt at the level of the cricoid cartilage. The tube suddenly passes on and is held up again for some seconds (it may be over a minute) at the cardiac orifice. This suddenly gives way and the tube passes into the stomach. After it has been in five minutes it is withdrawn and it can be felt to be gripped by the sphincter. This makes him believe that it is a true spasm and not an achalasia.

DISCUSSION ON HOSPITAL CONSTRUCTION IN THE LIGHT OF CROSS-INFECTION

Dr. A. G. Watkins: The facts on which this paper are based are largely taken from the recent enquiry, made at the instigation of the British Pædiatric Association (Allison *et al.*, 1946; Watkins and Lewis-Faning, 1949), to try to ascertain the exact incidence of cross-infection in children's wards in hospital. The following definition of cross-infection was used namely: "To denote any infection acquired by a patient in the hospital environment. Clinically it is an infection arising during the course of another illness from which the patient was originally admitted to hospital, and may attack the respiratory tract, gastro-intestinal tract, wound, scar or mucous membrane, or be manifest as one of the specific fevers." The enquiry covered children in 26 wards in 14 hospitals in Great Britain and the net finding was that of just under 10,000 admissions in 1947 there was an incidence of cross-infection amounting to 7% of all admissions. The wards were in charge of consultant pædiatricians and in the main were located in teaching hospitals. This should therefore imply that 7% is a minimal figure for the country as a whole.

The source of infection is usually that of an infected individual admitted to the ward as a patient or an infected attendant. The severity of infection will depend on the extent of the dose passed on, the virulence of the organism and the condition and age of the host receiving it.

The methods of spread are mainly by droplet infection and by direct contamination by handling infected persons or material. A sneeze is a common way by which droplet infection is conveyed to the air in a ward and so infecting the dust. This contaminated dust and air convey the organisms or virus and their passage is increased by movement such as during the process of ward dusting and bed making. Contamination by handling can readily occur when changing napkins, dressing wounds, or if the attendant's skin is harbouring an infection such as a boil or septic finger.

The problem is then, firstly, to prevent the infected persons from contaminating the air and dust and secondly to prevent the air and dust conveying the infection. In the prevention of the accumulation of dust the architect can be of great help. We have known for years that hospitals should never have corners and all nooks and crannies should be avoided. That is of vital importance, but, in addition, we have learnt and are still learning other techniques to reduce dust. Wet-sweeping of ward floors so that dust is collected in lumps and not dispersed in fine particles is of value and oiling of the floors with spindle or white oil helps considerably although not too popular with matrons. Blankets may be oiled so that dust from them during bed making is reduced but this will require special laundry facilities. There is some evidence that washing baby's woollies in the ward by the nursing staff, which is done to avoid shrinkage by the laundry, may not completely eradicate infection.

Considerable advances are being made in air purification and hygiene (1948) but we have not adopted air-conditioning widely in this country. On a visit to a Children's Hospital in New York it was disastrous to find that the ward had to be closed while the air-conditioning plant was being repaired and that as this was during the very hot weather it was quite impossible to open the ward at all.

Disinfection of the air by aerosols is another method of which we have not a great deal of experience here. The practical difficulty is that the substance to be sprayed may be more irritant to the patient than to the organism and aerosols are best used in air-conditioned rooms.

Ultraviolet-ray screens seem to be valuable and are used quite extensively in the United States and Canada. Their use may avoid infection by way of a swinging door which tends to draw air in from a contaminated corridor. They are expensive to erect but reasonably cheap to maintain.

There is no doubt that good cross-ventilation is one of the most important preventive measures we have to keep air from carrying infection. Plenty of open windows with good balcony space are an excellent insurance against cross-infection. It has been shown that ordinary sunlight has some germicidal effect on the dust in the ward.

If a patient has an infection which is liable to be spread it is obvious that he should be isolated from the rest of the ward, and the habit has grown of recent years of dividing children's wards into cubicles to allow individual isolation. In order to be successful cubicles must imply full barrier nursing and each cubicle must be self-contained with the necessary facilities for washing and for a nurse to keep and change her gown and masks. Cubicles should be erected so that they go up to the ceiling. An eight to ten foot barrier is of little use for several reasons. Firstly, a tall nurse can spray her droplets over the top. Secondly, a child standing in his cot is not always averse to spitting over the top or at least throwing toys over the top. Lastly, it is obvious that air contaminated in one cubicle can pass readily to another unless completely shut out. The only time that a cubicle not reaching the ceiling is at all justifiable is if this is the only means for its ventilation. There is one ever-present danger of cubicles. That is that the nursing staff must not think that because a child is secluded in a cell that the ordinary barrier precautions can be relaxed.

Architects can be of great assistance in the designing of these cubicles and above all they can help to ensure that ward units are not too big. By reducing the number of children into small units nursing is better and easier and cross-infection lessened.

Perhaps the most important aspect of the prevention of cross-infection is in the nurses and their training. By this is meant not only the instructions to wear masks and gowns but also training by special education, special lectures and demonstrations so that the nurse can really understand why these seemingly finicky regulations are essential.

There is one nursing danger which seems to be difficult to solve and that is the usual shortage of nurses during night duty. So often one finds that at night one or two nurses are expected to deal with the same number of babies as six or more nurses do during the day; no wonder that minor details of barrier nursing and general precautions tend to get neglected.

Masks should be worn by all who come in contact with small babies—by the doctor no less than the nurse. The mask, however, must be effective and must contain an impermeable layer. It is uncomfortable to wear, particularly when talking to students, but there is no question as to its value, so it should be used, but to be effective it must be used properly.

Acute specific fevers occur by no means uncommonly in a children's ward, and the enquiry referred to revealed that many children are admitted to the wards during an incubation period. In addition to this, children with sore throats or in contact with throat infection are taken in. Careful history taking and examination prior to admission are therefore essential preventive measures. This examination must, however, be done by a senior member of the staff. It is too responsible and too difficult a task to be left to a newly qualified house physician. Provision must be made in the way of a special well-lighted room in which to interview the parents and to examine the child.

At this stage Charts (not reproduced) were shown illustrating the paths by which infection travels; the dangers of ward sweeping and dressing times; the relative incidence of the various types of cross-infection; the increased length of stay in hospital occasioned as the result of cross-infection; and deaths attributed to cross-infection.

The prevention of cross-infection is a threefold problem. Firstly, the medical problem: hospital admissions should be examined carefully to exclude infection; children and especially babies must be protected against infection. Secondly, the help of the architect should be enlisted to design wards of small units, well ventilated and allowing of complete barrier nursing; and lastly it is on the training of the nursing staff that we must rely for the prevention of cross-infection.

WATKINS, A. G., and LEWIS-FANING, E. (1949) *Brit. med. J.* (ii), 616.

Dr. Thomas Bedford: There can be no doubt that infective material can be transmitted from one person to another *via* the air, but there seems to be no clear indication as to whether, in ordinary buildings, direct infection or airborne infection is the greater risk. In densely occupied rooms the risk of droplet infection will clearly be greater than in sparsely populated ones, but unless the ventilation varies in proportion to the number of occupants the concentration of airborne organisms will also tend to be greater with the denser occupation.

In *hospital wards*, where patients are in bed, it can be assumed that the chances of direct infection will be less than in, say, a factory or an office, and that in hospitals, therefore, aerial infection will be relatively more important. There is evidence that cross-infection in hospitals has been spread by the aerial route.

Much can be done to reduce the numbers of bacteria in the air by using either ultra-violet lamps or one or other of various disinfectant vapours or mists. These methods of air sterilization, properly applied, can be very effective against unprotected, single organisms, but they are less effective against dust-borne organisms. For ordinary wards, good ventilation, coupled with the efficient application of dust-suppressive measures, should do much to reduce the risks of cross-infection. It is true that Dr. Watkins and Dr. Lewis-Faning have recently reported that they could detect no significant association between ventilation and cross-infection, but this negative result leaves me unconvinced. The classification was made on the basis of replies to a questionnaire. Somebody at each of 14 hospitals was asked to give information concerning the quality of the ventilation in wards or cubicles, but there is no indication of the criteria used, or that any measurements were made.

Provision of ventilation.—Whether hospital wards are to be ventilated by natural or by mechanical means, a decision on the amount of fresh air that is to be supplied should be reached in the planning stage. Clearly, if the building is to be ventilated mechanically, the engineer must know what air supply is required before he can design his air ducts and decide on the sizes of fans. Even one with much experience of ventilation will be unable to say with precision what amount of ventilation will be obtained with any arrangement of open windows, but he can probably make a fair guess. Nevertheless, even with natural ventilation a decision must be made about the amount of ventilation to be provided during winter, for the heating engineer must make proper allowance for this in his calculations of heat requirements. If inadequate allowance is made ventilation must be restricted or the wards will be cold.

In the 1937 Report of the Departmental Committee on the Cost of Hospitals and other Public Buildings some guidance on this point is given to engineers. It is suggested that when ordinary convective methods of heating are used allowance should be made for 3 air changes per hour, and that when radiant heating is used this amount may be reduced to some extent. By the standards for ordinary buildings these suggestions allow for good ventilation.

A ventilation rate of 3 air changes per hour does *not* mean that the air within the room is completely renewed three times each hour. Instead, it means that the volume of air entering and leaving the room in one hour is three times the volume of the room. As the air enters the room it mixes to greater or less extent with the air already in the room, so that if any polluting agent is present in the room atmosphere it is gradually diluted by the ventilating air. If mixing is perfect, after the time taken for one air change—twenty minutes in our example—the concentration of the polluting material is still 37% of the original value.

The other basis on which ventilation calculations are made is that of the fresh air supply required for each person. In ordinary practice a fresh air supply of 1,000 or 1,200 cubic feet per person per hour represents good ventilation in cold weather. Now in a factory, where the cubic space available for each person may be only 400 cubic feet, 3 air changes per hour would give 1,200 cubic feet of fresh air per hour for each person. On the other hand, in a hospital ward, where the space allowance is probably 1,000 to 1,500 cu. ft. per patient, 3 air changes per hour represent 3,000 to 4,500 cubic feet of fresh air per hour per person. This seems to be a very good figure, judged by ordinary ventilation requirements, and it makes a considerable demand on a heating system, yet it may not be good enough to be effective in preventing cross-infection.

If the atmospheric contaminant which has to be removed by the ventilating air is being steadily emitted at a more or less constant rate which is proportional to the number of occupants—as, for example, the carbon dioxide in expired air—then the ventilation standard should be in terms of the amount of fresh air required per person, irrespective of the space allowance for each person. Such a standard might be desirable from the standpoint of cross-infection if the infective material were being disseminated more or less constantly by each occupant.

If, on the other hand, there is, perhaps, only one patient in a ward, who may occasionally eject highly infective material, a ventilation rate in terms of the number of air changes per hour is the standard which should be adopted—and the standard may need to be high.

With 3 air changes per hour, twenty minutes after the sudden introduction of some atmospheric contaminant the concentration of that contaminant is still 37% of the original value, if the contaminant is removed only by the ventilating air. After the same interval of time the residual concentration with 6 air changes per hour is only 14%, and with 10 air changes per hour 4%. These calculations make no allowance for the rate at which bacteria-laden particles will settle out from the air. When such allowance is made the contrast is less striking. It is probably reasonable to assume the rate of removal of particles by sedimentation to be about that which would be achieved by a ventilation rate of 4 air changes per hour. If we accept that figure, with an actual ventilation rate of 3 air changes per hour, ventilation and sedimentation together would remove bacteria-laden particles at a rate corresponding to 7 air changes per hour, and with ventilation at 6 air changes per hour the removal rate would be equivalent to 10 air changes per hour. With these removal rates the bacterial concentrations five, ten and twenty minutes after the dispersion of the organisms would be 56, 31 and 10% of the original concentrations with the ventilation rate of 3 air changes per hour, and 43, 19 and 3½% with ventilation at 6 air changes per hour.

It may be thought that the higher ventilation rate is desirable, but, if so, it should be allowed for when the heating installation is planned. I understand that it is recommended that heating arrangements should provide for the maintenance of a temperature up to 30° F. in excess of the outside temperature. Thus, except on relatively few days, when the outside temperature is below 35° F., it should be possible to maintain a temperature of 65° F. in the wards. To me this seems a reasonable temperature. Overheating is undesirable, but the wards should be adequately warmed. A 30° F. excess above the outside temperature will only be possible, however, if the ventilation rate is limited to that for which the engineer has made allowance—generally 3 air changes per hour. Increased ventilation in winter will be got at the expense of lower temperatures.

Some systems of heating set up steep temperature gradients so that the air around the head is several degrees warmer than that near the floor. Such a condition gives rise to complaints of cold feet and of stuffiness in the head. Similarly, a system of radiant heating which exposes the heads of the occupants to an undue amount of radiant heat is undesirable. Heating by steam radiators, especially when high-pressure steam is used, sets up more marked gradients than do hot-water radiators. In many buildings radiant heating by means of low-temperature ceiling panels has been used with much success, but ceiling panels should not be used in low ceilings unless their temperatures are really low. We are working at present on this problem, but it is too early to give precise guidance as to the maximum desirable temperatures of overhead panels.

Endemic Hepatitis Among U.S. Troops in Post-War Germany

By JOHN R. PAUL, M.A., M.D.

(*From Yale University School of Medicine; and the Commission on Virus and Rickettsial Diseases, Armed Forces Epidemiological Board, Office of the Surgeon General, U.S. Army, Washington, D.C.*).]

THE subject of Endemic Hepatitis may not be very appealing because with the war well behind us, many might like to say, "Allow us to forget about hepatitis, particularly military hepatitis". But I would point out that British investigators[1] are prominent among those who have dragged this disease into the open and we should get on with it.

We in the United States have been concerned with the fact that the incidence of hepatitis among U.S. troops within the American zone in Germany has not only continued to be high but has even been rising until it is to-day comparable to that noted in certain combat areas during the war, with an average of 14 cases per 1,000 per annum. Hepatitis has been a scourge to our military forces since 1942. During World

[1] I refer here to the work of W. N. Pickles, G. M. Findlay, F. O. MacCallum, W. H. Bradley A. M. McFarlan, and others.

War II it "fell like a bombshell" on the U.S. Army, which was hardly prepared for it. The first "bombshell" was the outbreak of homologous serum jaundice, which will hereafter be referred to as serum hepatitis (SH), for which inoculations of yellow fever vaccine were found to be responsible at that time. Then in 1943 and again in 1944 came large outbreaks of infective hepatitis (IH) in the Mediterranean area, in which British forces were also involved. From experimental work on the disease, which emerged from several laboratories at that time (and will not be quoted here in detail), it became apparent that at least two viruses were concerned: one responsible for infective (or infectious) hepatitis representing the naturally occurring disease; and the other responsible for serum hepatitis, apparently an artificial disease. The two diseases give approximately the same clinical picture and often appear intermingled at the same time and place. With infectious hepatitis (IH) there is a relatively short incubation period (fifteen to thirty days); contact cases are common, and the virus is found both in the fæces and blood during the acute stage and can be transmitted orally. With serum hepatitis (SH) the incubation period is much longer (fifty to one hundred and twenty days); contact cases are uncommon; virus has been detected only in the *blood*, during the incubation period as well as the acute stage, and transmission has so far been accomplished only through parenteral infection. There is no demonstrable cross immunity between the two viruses, and attempts to transform one into the other have, I believe, been entirely unsuccessful. Both diseases can be transmitted by needles or other instruments. While the *origin* of infectious hepatitis may not be particularly clear, that of serum hepatitis is completely shrouded in mystery. Whatever its origin may be, however, it obviously did not start in a syringe. The syringe merely seems to be an effective, mechanical vector.

From an epidemiological standpoint, infectious hepatitis appears to be world-wide in distribution. There are, however, certain geographical areas where rates in immigrant troops have consistently been high. Thus China, the South Pacific, the eastern half of the Mediterranean area, Italy, and also southern Germany are places where the hepatitis rates were particularly high in U.S. troops during and following World War II. This high "icterogenic capacity" characteristic of some geographical areas may not necessarily be reflected by the local civilian hepatitis rates, for the endemic disease in civilians is often poorly reported.

From a seasonal standpoint, the autumnal rise in the morbidity rate is a characteristic feature of infectious hepatitis. During World War II the hepatitis rates in U.S. troops in North Africa and Italy rose sharply in 1943 and 1944, in October. This same autumnal rise has been characteristic of the civilian disease in Denmark and Sweden. It may be of some significance, therefore, that seasonal fluctuations of hepatitis in U.S. troops in post-war Germany have not shown this sharp autumnal peak but instead an ill-defined double peak—occurring in the autumn and early winter respectively. Furthermore, this is contrary to the single autumnal peak seen among British troops in their zone in post-war Germany. The question arises, therefore, as to whether cases of serum hepatitis may not be frequently intermingled with those of infectious hepatitis in the U.S. troops to produce this different seasonal picture. Actually the existence of serum hepatitis has been proven experimentally to be present among these military cases.

As for seasonal fluctuations of serum hepatitis, it might seem that there is no particular reason for such to exist. But there are some data on this, available from Ruge's studies in the 1920s in Germany, on "salvarsan jaundice". His clinical material largely came from the German Navy and he found that the highest incidence of the disease in patients, who were receiving antisyphilitic therapy, occurred in January. One speculates as to whether or not his January peak may not have been related temporarily to the high autumnal peak of infectious hepatitis indicating a two-month lag between the two peaks, which is a period of time perhaps comparable to

the long incubation period of serum hepatitis. If this explanation were correct, one would assume that a closer relationship between infectious hepatitis and serum hepatitis exists than has heretofore been thought to be the case. Thus the theory that serum hepatitis virus may conceivably be a variant or a relative of infectious hepatitis virus could be based on the speculation that the two diseases seem to occur simultaneously or consecutively in time and place.

As to other details with regard to hepatitis among U.S. troops in the American zone of Germany, the disease has occurred most frequently in young individuals who have been in the area a relatively short time, with cases developing around the ninth to the tenth month of service. The cases have been quite sporadic in distribution. The incidence has been about the same among coloured as in white troops and has borne no special relation to service or rank.

Investigations have been made to try to determine whether the immunization of troops or the administration of penicillin could have contributed to the spread. There is some evidence that men with hepatitis have had a greater penicillin history than others but the data are not particularly convincing.

Summary

Evidence has been presented to indicate that infectious hepatitis has been prevalent and endemic in Germany for many years, particularly in Bavaria. Therefore it is not surprising that this disease should have been common in the U.S. Army of Occupation during the post-war years, 1946–50. It has been our suspicion that many, if not the majority of, U.S. soldiers who acquire hepatitis in Germany, do so as a result of direct personal contact with German households. But coupled with the natural disease, it would also seem probable that the infection has been maintained in this military population by the artificial transmission of both infectious hepatitis as well as serum hepatitis, via syringes and needles. The evidence for this is largely circumstantial but it has been proven experimentally in one instance, and there is considerable ground for suspicion that it is a frequent occurrence. Thus the seasonal curve of hepatitis among U.S. troops has more or less consistently shown some deviations from the usual autumnal rise and early winter decline of infectious hepatitis cases as seen in civilian populations, and among troops in combat previously and elsewhere. These deviations are compatible with the idea that some or even many of the winter cases are examples of serum hepatitis. If this conclusion is correct, it lends weight to the idea that serum hepatitis and infectious hepatitis are more closely related to one another than previous experimental work has perhaps indicated.

I have to thank our Military Authorities for permission to publish.

Adeno-fibroma of the Fallopian Tube Undergoing Malignant Change.—DOUGLAS MACLEOD, M.S.

This term is suggested for an unusual tumour of the fallopian tube which histologically was seen to consist of large masses of epithelial cells, some of which appeared to line branching clefts. These clefts were surrounded by a network of stroma cells. The epithelial formations and the stroma cells both showed malignant characteristics. The tumour was pedunculated, roughly oval in shape and lying in the lumen of the tube; it measured 6 cm. by 3·5 cm.

The pedicle was found histologically to be invaded by malignant tissue as far as its base.

The tumour occurred in a woman aged 55 who had had a radium induction of the menopause six years previously ; her only symptom was pain over the site of the tumour.

The patient died 14 months after operation from extensive sarcomatous deposits on the peritoneum.

Congenital Diverticulum of the Uterus Revealed by Uterosalpingogram.—DOUGLAS MACLEOD, M.S.

A case of congenital diverticulum of the uterus in which a recent pregnancy had occurred was demonstrated by uterosalpingogram. The first, taken nine days after the miscarriage, showed a circular diverticulum, 3·25 cm. in diameter, springing from the uterine fundus near the right cornu. In the second salpingogram, taken nine months later, the diverticulum had reduced in size to that of a pea. The patient had had three, previous, normal labours.

Subtotal Vaginal Clamp-Hysterectomy for Chronic Inversion of the Uterus.—I. BIERER, M.D.

Mrs. A. P., aged 57, was admitted on February 9, 1946, to Bethnal Green Hospital as an emergency case. She had had three children, no miscarriages. Regular periods; but for the last twelve years intervals of from three to six months between them. For the last six months she had felt something hanging down from her vagina and had recently had a copious vaginal discharge and heavy uterine bleeding. For the last twelve hours she had had severe hypogastric pains and had fainted on the day of her admission to hospital.

On admission her temperature was 97·6°, pulse 76, B.P. 130/90, her normal B.P. being 220/140. She was suffering from a moderate degree of shock. The patient had always been a very healthy woman, her weight being 17 st. 7 lb., and her height 5 ft. 5 in.

The gynæcological examination of this patient revealed a mushroom-like tumour, the size of a Jaffa orange, protruding through the vagina, which was rather tender, congested, and unhealthy in appearance with a fibroid on the top of the mass. The lower abdomen was tender too. The patient was prepared for the theatre, and an examination under anæsthesia was performed. A metal catheter was introduced into the bladder and a finger into the rectum. They met readily without interference by the uterine body, therefore the diagnosis chronic inversion of the uterus was made.

Chronic inversion of the uterus is rare ; complete inversion is rarer still. In the majority of cases it is puerperal in origin, commencing as an acute inversion. In a minority of cases it is due to the presence of a tumour, a submucous fibroid, a sarcoma, or a carcinoma.

The most suitable method of treatment in these usually infected cases seems to be vaginal hysterectomy with drainage. The maximum drainage is achieved by clamp-hysterectomy. In this case a subtotal vaginal clamp-hysterectomy was performed.

Pryor-Kennedy's clamps were applied to each side of the protruding mass after a small incision had been made first on the posterior and then on the anterior wall of the inverted uterus.

The body of the uterus was amputated, the widely dilated cervix being left with the four clamps which were finally removed after seventy-two hours. A vaginal plug was inserted for forty-eight hours.

The patient's temperature did not exceed 100·2° for a few days. She made a smooth recovery and was discharged on March 12, 1946. She was last seen on February 28, 1949. The cervix was closed and there were no visible marks of the operations. The patient felt well.

Vaginal clamp-hysterectomy provides excellent drainage, the powerful Pryor-Kennedy's clamps will prevent retraction of vessels and there are no ligatures to slip. There is no danger of pulmonary embolus (Kennedy and Campbell, 1944), the operation is simple and can be performed quickly.

Dicephalic Monster.—D. W. JAMES, M.B.

Specimen was shown with radiograph, autopsy report and historical review. The monster weighed 7 lb. and was delivered as a breech, with craniotomy of one after-coming head.

Uterine Irritability as a Cause of Dyspareunia.—EDWARD COPE, M.B.

In 1937 Dickinson described a clinical method by which it was possible in the healthy non-pregnant woman to detect rhythmic uterine contractions. He performed 89 pelvic examinations on 5 women during various phases of the menstrual cycle and found that the uterus was most active for three or four days before and three or four days after ovulation. During this period the uterine contractions occurred at intervals of from two to ten minutes. Following this the uterus was in a state of relative quiescence, but again became active a few days before the onset of menstruation and this activity continued during menstruation.

It is furthermore well known, as a result of work by Malpas, that even in early pregnancy the uterus undergoes regular contractions. This phenomenon was also described by Palmer (*Proc. R. Soc. Med.*, 1950, **43,** 99).

Stallworthy in his Address to the Royal College of Obstetricians and Gynæcologists, states that " previously unsuspected uterine irritability is the most common cause of tubal occlusion "; he further states that " the female genital tract is the most hysterical portion of a woman's anatomy. . . . It manifests its independent rebellious spirit in a multitude of ways; the so-called functional or intrinsic dysmenorrhœas, vaginal spasm and vaginismus, to mention but some of the common manifestations of this disharmony ".

The following is a short account of 3 cases in which this disharmony is manifested by a uterine irritability of such a degree as to cause severe dyspareunia.

The first case was the wife of a publican. A nullipara aged 50. Menopause twelve years ago ; no post-menopausal bleeding or discharge.

She complained of severe mid-line lower abdominal colicky pain which occurred only after orgasm, and lasted half an hour, but that as orgasm was the usual sequel of intercourse, and as her pain was severe, her life was being made miserable.

The only significant incident in her previous medical history was that eleven years ago she had had a dilatation and curettage for an intra-uterine polypus. The records of this operation were not available. She thought that the pain of which she complained dated back to this operation, but it was only in the past two to three years that it had become really severe.

She was a healthy-looking, well-built woman, and apart from a blood pressure of 180/100, nothing abnormal was found on general medical examination.

Pelvic examination revealed that she had a mobile retroverted uterus and that the left ovary was cystic and enlarged to the size of a pullet's egg. Nothing else abnormal was felt. A diagnosis was made of post-coital pain due to strong uterine contractions.

In view of the severity of her symptoms it was decided to remove her uterus. At operation it was found that the uterus was slightly enlarged, and that there was a small subserous fibroid in the posterior wall. The ovarian cyst, which had been palpated, proved to be a small serous cyst of the left ovary. Total hysterectomy with bilateral salpingo-oophorectomy was performed. Examination of the uterine cavity revealed a friable irregular polypoid mass $5 \times 3 \times 1$ cm. in size which appeared to invade the myometrium and which on section proved to be an adenocarcinoma of the body of the uterus. The patient made an uneventful recovery and intercourse is now satisfactory.

It seems probable that this patient had an irritable uterus, and that the increased tension in the uterus due to the intracavitary tumour increased the strength of the uterine contractions to such an extent that they caused severe pain. This is in accord with the work on uterine tension by Reynolds and by Knaus, who found that an increase in the volume of the uterine cavity by only 3 – 4 c.c., raised the uterine tension sufficiently to increase the strength of the uterine contractions.

The second case was a nullipara aged 19 who complained of similar pain following intercourse. Examination revealed nothing abnormal. A diagnosis of uterine irritability was made and pethidine 100 mg. was prescribed, to be taken before intercourse. This relieved her pain and she became pregnant during the next menstrual cycle.

The third patient was a para-1, aged 34, who complained that for the past five months she had had colicky hypogastric pain on intercourse. She had also had menorrhagia since the birth of her baby two and a half years ago. Examination revealed nothing abnormal but in virtue of her symptoms a diagnosis of uterine irritability associated with an intra-uterine polyp was made.

Dilatation and curettage was performed and an endometrial polypus was removed.

Dickinson states that in women: "The much exploited (uterine) rhythms in orgasm fall into the class of erotic fiction until evidence by trained observers is submitted." Although the uterine contractions were not palpated in any of these cases, their histories and the results of treatment indicate that their symptoms were due to uterine irritability.

In 2 of these patients there is an additional factor which would be likely to increase the strength of uterine contractions stimulated by intercourse. If it is a fact that intercourse may in some women stimulate uterine contractions of such a degree as to cause pain, then the implications are considerable in infertility, abortion, particularly at the so-called critical period when the progesterone level may be reduced, and in the diagnosis of intra-uterine tumours.

DISCUSSION ON RESUSCITATION OF THE NEWBORN

Dr. J. Edgar Morison (Belfast) : The pathologist must first try to decide what proportion of infants die because resuscitation procedures fail. When death is due to congenital anomalies, to birth trauma, to infection and to various other conditions it may be preventable, but scarcely by procedures which are now to be reviewed. These conditions all produce recognizable and often highly distinctive structural changes but many other fœtuses and infants do not show these lesions.

The absence of these lesions and the presence of certain other less specific changes suggest that these children die only because they are exposed to conditions in their intra-uterine or extra-uterine environment which themselves directly produce fatal anoxia. Such an extrinsic or environmental anoxia may be due to some insufficiency of placental transfer, a misfortune of the mechanics of labour, some disaster to the cord, or an environmental accident, such as the aspiration of excessive amounts of amniotic sac debris or mucus into the air passages. This anoxia always favours birth trauma and infection, but by itself it may be responsible for death. This may be recognized by grouping together for further analysis all deaths which are due to anoxia alone. If these children are born alive, that is with pulsating umbilical vessels, their failure to live is a failure of resuscitation avoidable or unavoidable.

As thus defined the importance of asphyxiation in intra-uterine and extra-uterine life can be seen from Table I derived from an analysis of 1,074 cases all of viable maturity from our in-patient hospital services (in Belfast) recently studied with complete routine histology from every organ of the body.

The causes of anoxia, or at least its immediately precipitating causes, can sometimes be discovered by a review of obstetrical details and autopsy observations. In Table II intra-

partum stillbirths are analysed. Often this is only to introduce one stage further back an unknown cause, often it is only to provoke endless discussion on the right or wrong management of a case. Especially as term approaches the oxygen requirements of the fœtus are dangerously close to the maximum the function of the placenta can provide. The functional reserve of the placenta must vary considerably from fœtus to fœtus, but it is often dangerously small for a difficult or prolonged labour. Until more is known of how to measure this reserve any comparison of one case with another, or one procedure with another, is incomplete. Only comparisons between large, carefully selected and comparable groups are valid.

When liveborn infants are considered, the basis of the failure to establish respiration is often anoxia due to some such insufficiency commencing in intra-uterine life. It is complicated by various factors concerned with pulmonary respiration and with the establishment of the circulation of extra-uterine life. First there is the maturity of the newborn infant (Table III).

TABLE III.—DEATH: THREE DAYS AND UNDER BY MATURITY (PER CENT)

The handicaps of the premature infant could be discussed in great detail. Only rarely and in very premature infants do they render extra-uterine life impossible. These handicaps include a simple lung pattern with resultant lack of surface for interchange between air and blood, the paucity of pulmonary blood vessels and their separation from air spaces by groups of cuboidal epithelial cells. Irregular expansion of air spaces is contributed to by the scanty elastic tissue in the immature lung. Other disadvantages include immature respiratory centres, weak muscles of respiration and poorly supported blood vessels which rupture readily and lead to asphyxial hæmorrhages, such as those which sometimes rupture into ventricles of the brain. Other factors which should be considered are concerned with the intra-uterine aspiration of amniotic sac debris. Premature infants especially seem unable to eliminate this material from the respiratory passages, and, in their œdematous lungs, its movement in air currents at least contributes to the formation of hyaline membranes. These in turn produce extensive secondary atelectasis in the hours and days following birth. These factors must all be allowed for in any assessment of the value of resuscitation procedures.

Some asphyxiated fœtuses are born showing the effects of an asphyxia which has existed for only a few minutes before their birth. Usually their resuscitation is an immediate success or failure, though a few may succumb later because they have aspirated vernix debris which may form hyaline membranes or because of infection. In another group intra-uterine asphyxiation has continued longer, metabolites of imperfect tissue metabolism in the fœtus have altered the permeability of capillary walls and fluid has passed into the extravascular space. There is œdema of all loose connective tissues, œdema of the stroma of the lung and perhaps, though it is difficult to demonstrate satisfactorily, œdema of the brain. The fœtus differs from an organism living an independent existence. There, until the capillaries are severely damaged, only limited amounts of fluid may pass from the blood into the tissue spaces. In the fœtus transfer of water and salts across the placenta occurs freely and the relatively large blood volume of the mother may permit much larger amounts of fluid to pass to the

extravascular space of the fœtus with little fœtal hæmoconcentration or disturbance of osmotic pressure. For this and other reasons, and especially in premature infants, intra-uterine anoxia causes œdema fluid to accumulate readily and in large amounts in fœtal tissues. The outcome of resuscitation in these infants is often long in doubt, though sometimes it is their subsequent course which gives more anxiety than their first breath. Amniotic fluid is poorly absorbed from the lungs as air enters after birth and fluid readily re-accumulates in the air spaces, oxygen transfer from blood vessels to tissue cells is impeded and metabolism impaired. Whether any procedure more active than withholding fluid feeds from these infants is possible may be considered. The obstetrician listening to the fœtal heart during labour will also remember that it is not alone the severity of asphyxia, but also its duration which is important.

When an infant is born asphyxiated or heavily anæsthetized and in need of active resuscitation the higher respiratory centres are no longer active. The reception of, and response to, stimuli from skin, from muscle, joints, and from the blood-pressure rise following ligature of the umbilical cord are seriously diminished or absent, and carbon dioxide is present in excess in the blood in these cases. The onset of breathing too often depends on the stimulus of severe oxygen want and the response is an unco-ordinated inspiratory gasp. Progress in resuscitation depends on removing the depression of anoxia or narcosis from the respiratory centres, so that rhythmic breathing, mediated by the controlled activity of all the respiratory centres and by pulmonary reflexes, may occur. As long as the circulation continues any movement of oxygen into the air spaces of the lungs should be of benefit for this purpose. Certain procedures, such as rocking, mouth to mouth respiration or various machines may have certain advantages. A viable infant will, however, probably always gasp without such assistance, and those with prolonged experience have rarely retained that enthusiasm for these procedures which theoretical considerations might seem to justify. They probably increase the risk of infection and unless used with care they may produce a pulmonary interstitial emphysema or injure the liver. The operator is, indeed, always more important than the technique.

After birth much amniotic fluid has usually to be removed from the lungs, and though large amounts can be quickly absorbed by an adequate circulation, a slight downward tilt of the air passages will help, especially to eliminate particulate material. With this as a routine we have only twice found plugs of meconium in the air passages. Much of this had been drawn far beyond the reach of bronchoscopic aspiration in the few minutes these children lived.

The most important impediment to normal respiration is usually some disturbance of oxygen interchange in the lung. The anatomical basis for this may be considered. Fluid is last absorbed from, and first accumulates in the most peripheral parts of the respiratory tree. Within a lobule surface tension and not gravity dictates this distribution. Some degree of primary or secondary atelectasis is almost universal even in full-term infants. This also affects the peripheral portion of the air-space system. Both these disturbances reduce the respiratory surface disproportionately more than the volume of the respiratory tree. This involves a loss of opportunity for respiratory exchange which is disproportionately greater than the diminution of the air-space volume. The functional value of the available air space is therefore disproportionately reduced. It is almost impossible to assess these anatomical findings quantitatively or in terms of function, and assessment of their importance is made even more difficult because they tend to progress rapidly in the period immediately before death. Morbid anatomy urgently needs assistance from physiology. If the blood oxygen content is not to decline rapidly as these conditions progress we may expect the respiration rate, and even the volume breathed per minute by infants so handicapped, to be increased well above normal. However, this will probably only occur if the respiratory centres in the brain are intact. Only functional studies during life can indicate the time of onset, the probable extent, and the progress of these disturbances and thus guide our therapy.

Electrical Stimulation of the Phrenic Nerve

This is an interim report of a method of artificial respiration applied to newborn babies, which has recently been described by Sarnoff *et al.* (1948*a* and *b*) and Whittenberger *et al.* (1949) for animals and adult human subjects. In a series of papers they have shown that the phrenic nerve may be stimulated by a suitable current through the intact skin, and this will result in contraction of the diaphragm and marked inspiration. With modern electronic equipment a current may be applied which moves the diaphragm in a way which closely mimics normal diaphragmatic contraction.

The principle of causing respiration by stimulating the phrenic nerve is not new. In 1783, in his treatise for the Doctorate of Medicine of the University of Göttingen, C. W. Hufeland described the responses of dogs which had just been drowned to electrostatic

stimulation. He mentions the marked respiratory movements which occurred when the phrenic nerve was stimulated. Ziemssen (1857) applied a Dubois Reymond stimulator (shocking-coil) to the phrenic nerve of a man nearly dead of coal-gas poisoning, with successful results. Sansom (1865), in his book on chloroform anæsthesia, cites three references to successful use of the shocking-coil in cases of collapse under chloroform. Two of the cases show it was used with success in London at that time.

More recently, Israel (1927, 1928) applied the Dubois Reymond stimulator to the phrenic nerve in a series of cases of asphyxia pallida, and was successful in many of them after other more conventional methods of stimulating respiration had failed. He found that it was quite possible to stimulate the phrenic nerve through the intact skin of the newborn baby. He stated in his last paper that there had been no death in the University Hospital of Bonn from primary respiratory failure in the newborn in the six months during which the machine was in use.

The apparatus which I have used was designed by Mr. P. W. Roberts of the Physics Department of St. Mary's Hospital Medical School. It is an electronic device which has an output of negative-going rectangular pulses of 1-2 M/sec. duration, with an interval between the pulses of about 8 M/sec. During a stimulation the successive pulses increase in voltage towards a short plateau. The output impedance of the generator is approximately 1,000 ohms. There are independent controls of the period of stimulation to the period of relaxation, and the frequency of repetition of stimulation is also variable. The voltage which may be applied can be varied through wide limits, but a precise specification of this does not seem desirable until more experience has been gained in this method.

Case report (24.6.49) (Patient of Mr. Leslie Williams').—A primipara was delivered of a male baby at 9.45 p.m., after a difficult instrumental delivery *per vaginam*. The baby was pallid and flaccid on delivery and breathing, when it was established, was irregular and shallow. The air passages were cleared of mucus, lobeline was given into the cord, and oxygen was played on to the face. The infant was left in an oxygen tent and not seen by me until three and a quarter hours after birth, by which time it had twice been pronounced dead and the breathing consisted of single gasps at more than one-minute intervals. The stimulator was used with a large indifferent electrode placed on the back and the active electrode in the region of the phrenic nerve. After three-quarters of an hour of successful stimulation the baby was a good colour and breathing spontaneously. Up to the present time the child appears to be developing quite normally, both mentally and physically, and is being observed by Dr. Reginald Lightwood.

There are obviously many details of this method which are not yet known, and it is impossible to assess whether it should be used routinely for asphyxia in Maternity Departments. A further report will be made when this information is available.

Dame Louise McIlroy: The most dangerous age in our lives is the first twenty-four hours after birth. During labour more attention should be directed to the condition of the fœtus.

Infant mortality has been much reduced in the present century, but there has been little reduction, however, in fœtal and neonatal mortality.

A high percentage of deaths is due to anoxia or want of oxygen, both among premature infants and at term.

Some infants survive but die within four weeks from pulmonary and cardiac complications.

The term asphyxia is confusing. There are gradations from the milder forms of suffocation, due to obstruction in the air passages, to the severe type with heart failure; both are due to the deprivation of oxygen.

Blue asphyxia or apnœa is caused mainly by obstruction of the upper air passages by fluids, mucus, vernix or blood. This takes place before and during delivery. If respiration is retarded the infant passes into a condition of *white asphyxia* or *shock* owing to failure of the heart or its carotid and aortic accessories.

Apnœa as a rule is of short duration under skilled treatment.

Respiration may be delayed in some cases to ten to fifteen minutes provided the heart action is maintained, otherwise death takes place. In law a child is born dead if the lungs

do not function even though the heart may be beating after birth. Before delivery the fœtal heart may become irregular, rapid, followed by slowing down, and convulsive movements occur, as the fœtus endeavours to obtain more oxygen. Meconium in head presentations indicates paralysis of the anal sphincters.

The causes of asphyxia are very numerous.

During pregnancy many are preventable by efficient antenatal care, and investigation of the health of the mother.

Cephalic version carried out so frequently for restitution of breech positions endangers fœtal life. Spontaneous version takes place in most cases before the 36th week of pregnancy. Premature separation of the placenta is a common cause of fœtal death, and in placenta prævia is difficult to avoid, especially if there is operative interference.

X-rays should be more frequently employed to gain an accurate picture of fœtal conditions. Malpositions of the fœtus can be rectified in some cases by posturing the expectant mother in the late weeks of pregnancy.

During labour there is more danger to the fœtus if the mother is an elderly primigravida, or one who has had numerous children with short spacing in between. Prematurity and post-maturity, disproportion between the fœtal head and maternal pelvis, all contribute to fœtal dangers which may result in damage of the respiratory and circulatory intracranial centres.

Excessive uterine contractions diminish oxygen supply to the fœtus, also cord obstruction by prolapse or torsion cut off oxygen, as it is the only pipe-line of supply to the fœtus.

Narcotics and also anæsthetics, if deep or prolonged, should be given with great care and judgment. For the present nitrous oxide and oxygen seems to be the only safe method for light anæsthesia in the second stage of labour. One of its chief advantages is that it distracts the attention of the patient if self-administered. Giving oxygen to the mother is sometimes of benefit in overcoming fœtal heart distress.

During delivery the most frequent cause of anoxia is precipitate delivery by hurried and forcible efforts by the attendant if labour is prolonged. Forceps are the source of danger if the blades are misapplied to the head, and not relaxed during the intervals between uterine contractions. The result is often intracranial injury.

Extraction should be slow even up to twenty minutes. Forceps are much more easily applied and controlled if the patient is in the cross-bed lithotomy position, the operator remaining seated.

During delivery in every case as soon as the mouth of the child appears from under the perineum it should be wiped out by the finger covered with gauze, and the nose squeezed free of fluid. This prevents many cases of delayed respiration.

Management of the newborn.—As soon as the infant is born it is laid on its right side, and immediately covered by a warm coverlet to prevent loss of heat, as it loses heat by transference from the uterus to the air.

When the cord has ceased to beat and is separated, the infant is carried to its tilted warm cot. Lifting should be by one hand under the shoulders, and one under the buttocks with as little movement as possible. The head is lowered to allow fluid if present to pass out of the mouth with the infant lying on its right side. It is allowed to rest from its delivery, and later cleansed with olive oil and dressed.

No baths are given until the cord has separated—about the fifth day. The late Professor Pembrey of Guy's, on going round our wards in the Obstetrical Unit of the Royal Free Hospital, asked why we were so careful in our treatment of the premature infant by warmth and oiling and yet allowed loss of heat by bathing the ordinary infants. We therefore verified this statement by taking the rectal temperature of 100 newborns before and after the first bath, and there was a loss of 1–2° of heat.

Bathing was discontinued and all infants cleansed with olive oil with good results, and less loss of weight in the first few days after birth.

If fluid collects in the mouth or pharynx of the newborn it should be removed by the soft rubber catheter with a glass mouthpiece and inlet to see the rise of the fluid. A metal instrument may injure the soft tissues of the throat.

Complicated and expensive methods of blowing air into the trachea are as a rule only suitable for hospital practice and in skilled hands. They are not obtainable in domiciliary practice more especially in that of midwives.

If the infant still cannot breathe, or only by spasmodic efforts, oxygen (95%) and carbon dioxide (5%) should be given on a mask supplied by a small cylinder with safety pressure apparatus as devised for me by Siebe Gorman.

Lobeline ½ c.c. (as suggested to me by Professor Raper), when injected into the umbilical vein, acts as a stimulant and gives relief in some cases.

Further research is required by physiologists and pathologists into the cause of intra-uterine activity and asphyxia.

I feel convinced that any forcible method of artificial respiration is dangerous, further than

gentle compression of the chest by hand. If there is circulatory failure, massage of the heart by the hand under the ribs is of benefit.

Mouth to mouth inflation is only mentioned to be condemned. Its only advantage is that it may cause entrance of air into the stomach and so cause pressure on the diaphragm which may stimulate respiration. Sepsis and pneumonia has been the fate of some infants after this method of insufflation.

Resuscitation methods, such as that of Schultze, have caused deaths. Even hanging the infant up by the heels as advised in modern textbooks is dangerous, especially if intracranial injury is present, a condition which is difficult to diagnose.

We can only promote expiration at the best. Inspiration depends on the infant when we clear and stimulate the air passages.

[Part of a film was shown to demonstrate delivery in a normal case.]

Mr. J. B. Blaikley: I do not propose to discuss at any length the baby that is born in a state of moderate anoxæmia, and in whom, following the clearing of the airway, respiration is quickly established, but rather the baby which fails to breathe readily and which becomes limp, and in which the heart begins to fail, the condition usually termed asphyxia pallida. The factors responsible are, in varying degrees, prolonged lack of oxygen, shock, pain-relieving drugs such as morphia. Unless prompt measures are taken some of these babies will die, though admittedly many others will belatedly start to breathe spontaneously.

Mr. Gibberd and I (1935) studied the problem of resuscitation of the newborn in 1933, more particularly because of the difficulty in resuscitating babies delivered rather soon after morphia and scopolamine. I was disappointed in the effects of coramine (nikethamide) and the methods of resuscitation then in use. The logical answer seemed to be to inflate the lungs with oxygen, and the simplest way to do this seemed to be to pass an endotracheal catheter and blow the oxgyen in under pressure.

The apparatus we devised is simple and efficient. It consists of a small Magill's silk web catheter which can be passed into the trachea by touch, or with the help of a small laryngoscope, a 2-litre rubber bag connected to a cylinder of oxygen and CO_2, a T-piece inserted into the rubber tubing between bag and catheter to which is attached a manometer registering cm. of water. The bag being full, steady pressure is made on it with the hand up to 30 or 35 cm. of water. The bag acts both as a reservoir and also as a buffer which prevents any sudden rise of pressure in the lungs, which will rupture alveoli, as would be possible if the cylinder was connected straight to the catheter. The catheter should be size 3 or 4, one which leaves adequate space for the outflow of gas through the glottis. The pressure of gas in the lungs is half that in the bag. I have never had an accident, nor do I know of an accident at Guy's. The occasional accident reported has always been through omitting the bag, and connecting up the oxygen cylinder direct to the catheter.

I have now used this method for seventeen years, and on a number of occasions have found it invaluable. It is, I believe, the most certain way of resuscitating a baby, indeed I cannot recall a failure except where autopsy has shown intracranial hæmorrhage or there has been no sign of life at birth. In the knowledge that I can readily start respiration, I have felt happier about the use of analgesic drugs late in labour, and have therefore used them more freely, with advantage, I believe.

I have, during the years, changed my ideas about the way in which the method works. Autopsies on babies with intracranial hæmorrhage which have been insufflated show very little, or even no, expansion of the lungs, and I believe the improved colour which immediately follows insufflation and indicates relief of the anoxæmia, with the result that the pulse strengthens and spontaneous respiration commences, is due to absorption of oxygen through the mucosa of the trachea and bronchi. I have, however, on many occasions noticed that the passage of the catheter has caused immediate inspiration, apparently in a reflex manner; some of these babies after birth had made one or two inspirations and then apnœa supervened apparently as a result of inspiration of mucus. In such cases I often start by aspirating the contents of the trachea and bronchi through the catheter.

There is still much discussion as to whether oxygen or oxygen and CO_2 (5%) should be used. The general opinion is in favour of the former in view of the fact that there must already be a high CO_2 concentration in the blood, but on the whole I favour the latter. I always think that deeper inspiration results, with presumably greater expansion of the lungs; further I believe that many babies have been subjected to a high CO_2 concentration for many hours—in postmature babies, perhaps for many days—and that the medulla has become accustomed to this, so that a sudden marked fall in concentration is responsible for feeble respiratory movements. If this is so, it is necessary to maintain a high CO_2 level in the blood till respiration is well established.

Lobeline 1/20 or 1/30 grain I find very variable in effect and often it fails to induce inspiration; I have really given up using the drug along with all the others, and rely entirely

on the method of resuscitation I have described. It is very difficult to know whether there are any ill-effects of anoxia on the C.N.S. of the child in very severe and prolonged cases, and in actual fact they are probably very rare. There seems no sense, however, in taking chances and I will conclude by insisting that if a baby is born in asphyxia pallida no time should be lost in clearing the airway, and if the child does not breathe promptly then the lungs should be insufflated. The child's urgent need is for oxygen and the sooner the medulla is "pink" the sooner the respiratory centre will function and the failing circulation recover.

REFERENCE

BLAIKLEY, J. B., and GIBBERD, G. F. (1935) Asphyxia neonatorum, its treatment by tracheal intubation, *Lancet* (i), 736.

Dr. B. G. B. Lucas: It is first relevant to review fœtal respiration and some of the factors influencing its control. Ferroni [8] in 1899 published a graphic record of rhythmic movements obtained from the maternal abdominal wall and six years later, Ahfeld [1] demonstrated the same thing. Both authors were of the opinion that these movements were respiratory ones, but at the time, no interest was taken in their work and the results were ignored. It was not until 1937 that Snyder and Rosenfeld [22] were able to demonstrate respiratory movements in animals by exposing the fœtus under physiological conditions and directly observing it. The animals that they used were the guinea-pig, rabbit and cat, and, later, Barcroft [3] confirmed this by direct observation on the sheep. The conclusions of these writers are important, because by their study of intra-uterine respiration in animals they were able to demonstrate some of the factors controlling it. Firstly, that excess of carbon dioxide to the mother does not stimulate fœtal respiration, whereas a lack of it produces inhibition. Secondly, that the fœtus is very sensitive to the effects of narcotics and respiratory movements are abolished at a level of analgesia which does not impair maternal respiration. Snyder and Rosenfeld [22] also showed that anoxia in the fœtus never produces the initial respiratory stimulation, such as is seen in the adult, but is depressant in its action. From this, they concluded that the carotid body reflex is not present in the fœtus. This depressant effect of oxygen lack in the fœtus is logical because, were it not so, the actual process of labour might stimulate the fœtus to initiate big respiratory movements and so drown itself. As Barcroft [4] has pointed out, the fœtus behaves quite differently from the adult and it may be dangerous to make assumptions about the effect of anything on the one from the known effect on the other.

It is not yet clearly understood why the newborn child takes its first breath at all and having done so, why it continues. Preyer [19] in 1882 thought that the onset of respiration in the newborn was due to some nervous stimulation, such as contact of the skin with air. That stimulation of the fifth cranial nerve in the sheep fœtus will initiate gasping respirations has been shown by Barcroft [3]. The sudden freedom from continuous pressure immediately after birth may be a factor, but this would appear unlikely because in birds the newborn chick takes its first breath from the air sac at the top of the egg before breaking out of the shell, so that here the release of pressure occurs after respiration has started. Anoxia plays no part in the initiation of the first breath. This is demonstrated clinically by the fact that blue asphyxial babies do not breathe at once.

The relative resistance of the newborn to the effects of oxygen lack is important. Robert Boyle [6] first commented on this in 1670 when he noted that very young kittens survived longer than their mothers under asphyxial conditions. The newborn rat will survive one hour in an atmosphere of nitrogen without apparent ill-effect and the newborn dog and cat twenty-five minutes [7]. The explanation of the resistance is not clear. Himwich and others [11] have shown that the newborn brain has a greater store of carbohydrate than that of the adult and that this can be broken down anaerobically to provide energy for the cell. By injecting sodium iodoacetate, which prevents the breakdown of carbohydrate, into young rats and immersing them in nitrogen, they showed that their survival time was greatly diminished. In another series of experiments they found that hypoglycæmia reduced the survival time in nitrogen, whereas an increase in glucose prolonged it.

Another explanation for the resistance of the newborn to anoxia is that the fœtus may have a more efficient system of oxygen tissue enzymes than the adult which disappears within a few weeks of birth. In cyanotic congenital heart disease this resistance is maintained and although these children may remain undeveloped physically, mentally they are normal. They are also relatively resistant to the effect of the barbiturates and will tolerate twice the ordinary child dose without ill-effects. As barbiturates exert their action by inhibition of carbohydrate oxidation, it is possible that in the cyanotic child there is some alternative enzyme system which "boosts up" nerve cell respiration.

There are three fundamental causes of neonatal asphyxia: Intra-uterine trauma, fœtal anoxia, or maternal narcotics. White asphyxia is a more severe stage of the blue variety and

may be described as a state of severe shock. Windle and Becker [24] have shown that if the umbilical cords of full-term guinea-pigs are occluded for periods up to eight minutes, then the animals showed all the signs of blue asphyxia; longer times produced the white state. This change over from blue to white is sometimes produced in the very young under inadvertent asphyxial conditions. In the early stages the child is very cyanosed with a high blood pressure and a good pulse, but soon respiration fails completely. After a few minutes of respiratory arrest, the child suddenly becomes pale with an imperceptible pulse and appears to be near death. The exact mechanism of this is unknown, but probably in blue asphyxia the heart attempts to compensate by increasing its output, later a circulatory crisis occurs and the output falls. This explanation is true for the effect of anoxia on the heart of adults [23]. Narcotics, by depressing fœtal respiration and probably delaying the onset of the first extra-uterine breath, predispose to either blue or white asphyxia.

It is accepted that anæsthetic agents do produce a delay in the onset of newborn respiration. Any narcotic which has an analgesic effect on the mother must be depressant to the fœtus because narcotics achieve their action by an histotoxic anoxic effect on the central nervous tissue [20]. In spite of this, much clinical research is being carried out to find an analgesic drug which will eliminate the pain of childbirth but have no depressant effect on the baby. It is unlikely that such a drug will be found unless it is one that has so complex a molecular structure as to be too big to pass through the placental barrier. So far, all the present known analgesics are carried into the fœtal circulation. Because the fœtus absorbs a relatively large proportion of any anæsthetic agent given to the mother, the best of those now in use would be one which was either excreted quickly by the newborn baby or else destroyed. All the lipoid soluble drugs should be avoided as they are excreted via the lungs, but if they are used, chloroform, being the most potent, is the most efficient. The best agents are the gaseous ones, either nitrous oxide or cyclopropane. Nitrous oxide has two advantages. Firstly its method of administration is simple; secondly, any pure asphyxiating agent will have less effect on the fœtus than on the mother because of the difference in the dissociation curves of the two types of hæmoglobin, maternal and fœtal [15]. In 1941 Fazekas and others [7] showed that rat fœtuses delivered from mothers who had been killed with 5% oxygen in nitrous oxide respired spontaneously at birth. In favour of cyclopropane, a high percentage of oxygen can be given, so that at birth the newborn child should be fully oxygenated and its respiratory centre will only have to counteract the narcotic effect of the anæsthetic agent without the depressant action of ordinary anoxia. But, as the increase in maternal blood oxygen saturation will be small, the advantage to the fœtus will be minimal.

There are a number of other drugs whose analgesic properties in obstetrics might be investigated. The effect of intravenous novocain is not completely explained and its action may be partly peripheral. Some of the antihistamine group, e.g. benadryl, have considerable hypnotic activity and it would also be interesting to study the effect of some of the autonomic nervous system blocking agents, such as tetra-ethyl-ammonium bromide or the methonium compounds on obstetric pain.

The best method of resuscitation of the newborn must vary with the cause of the asphyxia. In the case of the blue variety, attempts should be made to cause maximum nervous stimulation of the respiratory centre so that the baby will expand its lungs of its own accord. The time-honoured method of stimulation of the skin, either by tactile or temperature change, is logical. Analeptics are to be condemned because unless they achieve their result immediately they stimulate the brain to produce a greater oxygen debt than it already has. The widespread use of analeptics in resuscitation has been cited [12] as a good example of the enormous resistance of the newborn to anoxia.

The administration of oxygen through a nasal catheter is valueless because the amount that can be absorbed through the mucous membrane of the pharynx must be very small. If it does achieve any effect, it is probably due to the nervous stimulation of the pharynx by the cold stream of gas. The protagonists of this method argue that when the infant does breathe, it will inspire pure oxygen. This is fallacious because, at the first gasp, the flow rate into the lungs will be rapid, much more than the 2–3 litres a minute passing through the catheter. Hence the oxygen will be enormously diluted with air. If oxygen is given, some form of mask and reservoir bag should be used.

Whether or not the umbilical cord should be clamped as soon as the child is delivered is a debatable point. Immediately after delivery there will be a small amount of oxygen obtained from the placental circulation. On the other hand, there is the stimulating effect of the clamp. It can be argued, with reason, that in the resuscitation of blue asphyxia there is no need for haste because the child's general condition is good. This is not true for the white variety, where there is a state of shock which should be treated by anti-shock measures. Presumably the cardiac output will be minimal and some method of increasing it, for example by transfusion, should be effective. Stimulation of the heart by itself is useless because in the shocked state there is an inadequate return. An auto-transfusion can be carried out by lowering the

baby several feet below the level of the mother before clamping the cord, so partially draining the placenta.

If the baby is known to be suffering from the effects of maternal narcotics, it is not only necessary to initiate the first breath, but also to continue stimulation to counteract the depressant effect of the narcotic. Here the analeptics may be of value, but after the first breath, which will expand the lungs, some mechanical device, such as a small Drinker apparatus, can be used [17]. The use of positive pressure ventilation is not without danger unless there is very accurate control. Owing to surface tension effects, the pressure necessary to inflate the atelectatic lung is greatly in excess of that needed to ventilate aerated tissue and, in lungs which may be partially expanded, this may disrupt already open alveoli without having any effect on the atelectatic parts. It is interesting to note that when a Drinker apparatus is used to inflate the lungs of a stillborn infant, the pressure needed is very high, much higher than that which the newborn could possibly achieve by itself [2]. How then does it manage to open its lungs at all? It may be by gradual active dilatation of its bronchial tree, starting at the larger bronchi and moving downwards with a wave-like motion so overcoming the surface tension effects and allowing the lungs to expand easily. This must be a nervous mechanism.

Carbon dioxide as a stimulant in the newborn is useless because not only has it been shown that high concentrations depress fœtal respiration, but also the respirationless child will already have a high body carbon dioxide.

Prophylactic measures might be of value in the treatment of asphyxia of the newborn. When analgesic drugs are used, a state of potential respiratory depression in the baby can be forecast. There may be evidence before birth of anoxia, the so-called fœtal distress. Under these circumstances, initial respiration at birth may be inhibited and if some method of preventing this could be found, it would be of great practical value. The protective influence of carbohydrate on the brain has been mentioned [11]. Suitable maternal diet in the later stages of pregnancy might increase this store in the fœtus. Again, intravenous glucose might be of use in the treatment of fœtal distress. Oxygen enzymes, such as cytochrome-c, might be of value to the mother in labour in the hope that they will pass into the fœtus and so enable it to utilize its oxygen more effectively. This has not been attempted yet, but cytochrome-c has been given to newborn guinea-pigs in an attempt to increase their survival time in nitrogen. So far the results have been somewhat equivocal [5].

The administration of oxygen to the mother will be valueless if it is only done for the last few minutes prior to the birth of the child because the giving of pure oxygen to the normal individual only increases the saturation of the blood from 98 to 100%, so that the effect of this on the amount in the fœtus would be small in spite of the different dissociation curve of fœtal hæmoglobin. But if it is given over a long period, then the nitrogen in the body will be eliminated and oxygen will replace it in the tissues both of the mother and of the fœtus, hence a bigger store will be available when the child is born. That the prolonged administration of oxygen does eliminate nitrogen from the body was demonstrated during the last war when it was used as a method of preventing "bends" due to the nitrogen bubbles which occurred at high altitudes in aircrew [9].

Regarding the effects of newborn asphyxia, much work has been done to show that it can cause permanent mental damage. Schreiber [21] collected 900 children who had had some evidence of asphyxia at birth and attempted to demonstrate that they had a higher incidence of mental defects than normal. Preston [18] in another series showed that they were mentally retarded. But in neither is the degree of asphyxia defined and the cases are not controlled statistically. Also the pathological picture that Schreiber [21] describes is in no way conclusive. Lund [14] noted a striking increase in postnatal complications in the asphyxiated babies in a series of two thousand deliveries. These three authors, however, all fail to mention the other factors of birth trauma and heredity in relation to mental development. In direct contrast, McPhail and Hall [16] found no evidence of mental abnormality related to asphyxia at birth in a group of 270 children. Again, Keith and Norval [13] followed up 111 children for four years, who suffered from neonatal asphyxia, and were unable to demonstrate any deviation from normal.

Since the newborn are so resistant to anoxia, it is unlikely that asphyxia does materially affect mental development, but final proof must await the result of an experiment with a large number of children, followed-up from the moment of birth until the age of 7 and the results assessed statistically, bearing in mind other variable factors such as heredity and the intelligence quotients of both parents; this is being done. An alternative would be to breed animals successively and selectively who have been subjected to asphyxia at birth and discover whether there were any mental deterioration.

Experimentally, pathological nerve-cell changes have been described [24] in full-term fœtuses deprived of oxygen by clamping the umbilical cord. This work, however, is not strictly comparable to that of ordinary newborn asphyxia because the animals were not only

deprived of oxygen, but also of any nutrient to their brain cells, so that anaerobic respiration could not take place. Nerve-cell changes following asphyxia are very difficult to assess from a histological viewpoint. Trauma to the brain while removing it, bad fixation or alterations in temperature prior to fixation, will all produce pseudo-anoxic changes. So any experimental evidence offered must be controlled under the most stringent conditions; with human material perfect control is impossible.

Mr. P. M. G. Russell (Exeter) showed a mechanical rocker designed to combine the principle of Eve's method of resuscitation with Gibberd and Blaikley's method of intratracheal oxygen which was in use at the Royal Devon and Exeter Hospital. The instrument was largely devised by Dr. Geoffrey Kelly of Torquay while resident anæsthetist and obstetric house surgeon at the hospital. The rocker is driven by an electric motor and incorporates a mechanism so that oxygen flows at a measured pressure during the inspiratory phase, i.e. while the baby's feet are descending, but is cut off on the reverse or expiratory phase when the abdominal viscera are pushing the diaphragm upwards.

The apparatus seemed to provide a method of resuscitation which was active without being violent and the results so far had been encouraging. What was so impressive was to see a pink colour gradually replace the previous pallor and cyanosis in the baby's face and when the motor was switched off the baby was found to be breathing tranquilly.

Mr. A. H. Charles favoured endotracheal insufflation with oxygen for anoxic babies when they did not respond to simple measures. He emphasized the need to have the apparatus ready, though it was seldom used, and showed photographs of a tilting platform upon which the baby is placed so that its head is level with the operator's chin. The baby is horizontal for the passage of the endotracheal catheter to which a two-way adaptor is fitted. The baby's head is lowered for tracheobronchial aspiration. By means of the two-way adaptor aspiration and oxygen insufflation can be carried out through the same endotracheal catheter.

Professor W. C. W. Nixon asked Dr. Morison if the hyaline membrane which he had found in the alveoli was present only in immature babies. He disagreed with Dame Louise McIlroy in her condemnation of pituitrin. Provided uterine contractions were properly recorded, the use of an intravenous pituitrin drip was very helpful in cases of inco-ordinate action of the uterus.

Dr. Morton, in reply, said hyaline membranes, though not lim ted to premature infants, were much more frequent in them. He attributed this to their greater chance of aspirating vernix debris, because anoxic complications more often arose before their membranes ruptured, and to their less satisfactory elimination of the debris from their air passages after birth.

Streptomycin in Urinary Tuberculosis

By ARTHUR JACOBS, F.R.F.P.S.G., and WALTER M. BORTHWICK, Ch.M.

THE object of this communication is to present some of the results obtained so far in a controlled trial of streptomycin therapy for tuberculous disease of the urinary tract. This investigation commenced at Robroyston Hospital, Glasgow, fifteen months ago under the auspices of the Tuberculosis Research Unit of the Medical Research Council and still continues. To date ninety patients have been studied. Selection of the cases for streptomycin treatment is made from a sequence of numbers taken from a statistically prepared list kept at the M.R.C. office where the name, age, sex and category of each patient is sent. Streptomycin has been given to 46 patients and 44 have been used as control cases.

It was decided at the outset to group the patients into five categories.

Group 1: Unilateral renal tuberculosis—minor lesion without cystitis.
Group 2: Unilateral renal tuberculosis—major lesion necessitating nephrectomy: cystitis.
Group 3: Bilateral renal tuberculosis—nephrectomy for the more advanced lesion.
Group 4: Tuberculosis occurring in the remaining kidney subsequent to nephrectomy for unilateral disease.
Group 5: (*a*) Major bilateral tuberculous lesions.
(*b*) Minor bilateral tuberculous lesions.

These categories comprise all varieties of renal tuberculosis excepting those suffering from tubercle bacilluria without a demonstrable renal lesion and those with unilateral lesions who become tubercle negative after nephrectomy. It was considered that it would not be possible to draw any conclusions, at least for many years, from the tubercle bacilluria group where no clinical lesions were demonstrated. It was also considered unjustifiable to withhold nephrectomy from patients with established clinical unilateral lesions and that no satisfactory information would be obtained by treating such patients with streptomycin if nephrectomy rendered them tubercle negative. A continuing residual cystitis with a tubercle positive urine however, places these patients in Group 2. Genital disease has not been studied unless it has happened to be coincidentally present.

The routine investigation carried out on every patient, whether treated by streptomycin or a control, is as follows. A tubercle positive urine is confirmed by direct smear, guinea-pig inoculation and culture. The separate kidney urines are similarly examined where their collection is possible. These tests are made before commencing treatment, on occasions during treatment, one month after completion of treatment and at two-monthly intervals during the follow-up which still continues. Cystoscopic and pyelographic (excretory and retrograde) examinations are likewise made before and after treatment. Intravenous urography by itself is inadequate for the demonstration of early lesions. Tests for streptomycin resistance are routine and assays of streptomycin levels in the blood are carried out. Observations on toxic effects with particular reference to vestibular damage are also made. It will be appreciated that an invesitgation of this nature entails a magnitude of work which is only possible by the combined efforts of an organized team.[1]

The patients treated by streptomycin are given 1 gramme daily in two intramuscular injections for ninety days. Controls and streptomycin-treated patients receive similar general medical treatment; tuberculin is not given to either set of cases.

Results.—In this preliminary report we are limiting our observations to the effects of the therapy on the urinary tract as ascertained by repeated bacteriological assays and by preliminary and follow-up cystoscopic and pyelographic examinations.

GROUP 1.—It is required of patients placed in this group that the lesion be a small one, yet demonstrable by pyelogram and that no appreciable clinical or cystoscopic bladder changes should have taken place. It was considered that this group would offer particularly favourable scope for observing the effects of streptomycin. A total of 15 patients were

[1]The following were the members of the team: Dr. A. M. Foulis, Physician—Superintendent, Robroyston Hospital; Mr. Arthur Jacobs, Consultant Urologist; Mr. Walter M. Borthwick, Tuberculosis Consultant; Dr. John C. Dick, Pathologist. Much assistance was also given by Dr. W. G. Wimsett, Senior Registrar and Dr. McKinlay, Oto-laryngologist.

classified as belonging to Group 1 and of these 7 received streptomycin and 8 were control cases.

Streptomycin cases.—Of the 7 patients treated by streptomycin, 6 became tubercle negative during treatment. One month after the cessation of treatment, one of these 6 had reverted to tubercle positive; three months after treatment another had reverted and in six months still another had become tubercle positive. Thus in a period of six months after the termination of treatment, 3 of the 6 cases which had first been converted to a tubercle negative phase, reverted to a tubercle positive one. It was noted that the 3 showing this favourable response had minimal pyelographic changes. In fact, if one had not been aware of a tubercle positive urine the pyelograms alone would not have sufficed for the diagnosis of a renal tuberculous focus.

The urine of the contralateral kidney became tubercle positive during or after treatment in 3 of the 7 patients and one developed cystitis. With regard to pyelographic changes, it was found that in one case the lesion had increased, whilst in one other the cavity tended to become shut off. The following is an account of the latter case:

A. S., male, aged 44. *Group* 1

This patient was admitted to hospital with a tuberculous elbow joint and found to have pyuria with a tubercle positive urine though without symptoms referable to the urinary tract. The bladder was of normal capacity and no cystoscopic changes were apparent. On pyelography the moth-eaten appearances of the upper calyces of the right kidney indicated a localized ulcero-cavernous lesion (Fig. 1). The urine from the right kidney was tubercle positive. The pyelographic appearances of the left kidney were normal and its urine was tubercle negative.

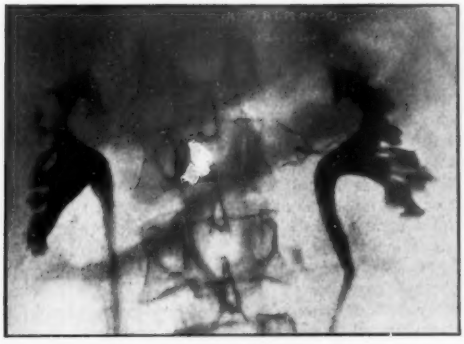

FIG. 1 (*Case A. S.*).—Bilateral retrograde pyelogram showing moth-eaten appearances of upper calyces, right kidney, indicating a localized ulcero-cavernous lesion.

FIG. 2 (*Case A. S.*).—Bilateral retrograde pyelogram one month after completion of treatment. The lesion in the right kidney has apparently become shut off.

Streptomycin treatment was commenced on March 21, 1949, and completed on June 18. One month later, retrograde pyelography indicated that the lesion had become shut off (Fig. 2). The pyuria had cleared and both kidney urines were tubercle negative on animal inoculation. The bladder urine was, however, positive. Four months later, pyelography showed the cavity in the upper pole still shut off but the kidney urine had reverted to a tubercle positive one (Fig. 3). There was no deterioration in the bladder, the elbow-joint lesion showed marked improvement, he had gained weight and the vestibular function was normal. Now, eight months after cessation of treatment, the left kidney urine as well as the right is tubercle positive and the pyelogram suggests the appearance of a lesion connecting with the upper calyx of the left kidney. The appearances on the right side are as before (Fig. 4).

It is apparent that the infundibular opening into the upper group of calyces of the right kidney has become constricted but not completely occluded and that the tuberculous focus itself has remained active. Treatment has not prevented the appearance of a tubercle positive urine in the contralateral kidney.

Control cases.—Conversion of the urine to tubercle negative occurred in only one patient, the total period of observation in this instance being three months. The urine of the contralateral kidney became tubercle positive during the period of observation in 2 of the 8 patients, while 4 developed cystitis. A deterioration of the lesion as shown by pyelograms was manifest in 4 instances. These results are summarized in Table I.

S=Streptomycin C=Control

GROUP 2.—In Group 2 were the patients who suffered from a unilateral renal lesion with associated cystitis. Each patient had the tuberculous kidney removed soon after the initial investigation had been completed and the operative procedure was always the same, being that of nephrectomy without ureterectomy.

Up to the present 25 patients in this group have completed a stay in hospital exceeding four months, so that each case has had at least one examination after the standard period of ninety days, whether that period was passed as a control or was spent under active treatment by streptomycin. In ten instances the follow-up examinations have been carried out more than six months after the observation period. Fourteen of the 25 patients were treated by streptomycin and 11 were control cases.

Streptomycin cases.—Of the 14 who had streptomycin, 5 were females and 9 were males. Conversion of the urine from positive to negative occurred in 12 and so far no reversion has taken place. The conversion was found in all these patients one month after the completion of the treatment and has persisted for three months in 3 and for six months in 1, and in 4 patients no tubercle bacilli have been detected in the urine during the eight months which have elapsed since the streptomycin treatment was discontinued. In the 2 patients who did not have a conversion of the urine, the tubercle bacilli have persisted for one and three months respectively after the cessation of treatment.

FIG. 3 (*Case A. S.*).—Bilateral retrograde pyelogram five months after completion of treatment. The focus in the right kidney is discernible but remains occluded.

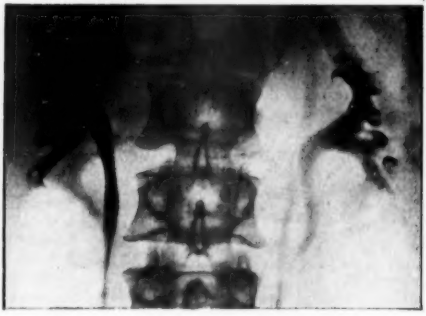

FIG. 4 (*Case A. S.*).—Bilateral retrograde pyelogram eight months after completion of treatment. The communication with the cavity in the upper calyx is still constricted. There is now evidence of an early lesion connecting with the upper calyces in the left kidney.

Cystitis was present in each of the 14 patients who received streptomycin and examination after treatment showed definite signs of improvement in 11 instances. In one other case the bladder mucosa was unchanged and in 2 cases of severe cystitis marked contracture of the bladder occurred soon after the start of treatment and cannot be interpreted other than as a worsening of the clinical state. This contracture persisted after the course of streptomycin was finished and was so marked that the patients were considered to be in need of transplantation of the ureter into the bowel. Of the 11 patients whose bladder condition improved the initial examination had shown slight cystitis in 5, moderate cystitis in 5 and severe cystitis in 1. The bladder mucosa became normal in appearance in 9 instances, 5 of which had previously shown slight cystitis and 4 moderate cystitis. In the 2 patients who did not have a conversion of the urine, the bladder mucosa was unchanged in 1 and greatly improved in the other.

None of the 14 patients has up to the present developed disease of the remaining kidney.

Control cases.—The 11 patients in this group, 5 females and 6 males, did not have streptomycin treatment for renal tuberculosis. The only one who received streptomycin was a man

who developed tuberculous meningitis and miliary pulmonary spread soon after the observation period started, but treatment was unsuccessful.

In the 10 remaining patients the initial examination showed the cystitis to be slight in 3, moderate in 3 and severe in 4. Conversion of the urine occurred in 2 of the 10 and has remained so for six and eleven months respectively. Both patients had an initial slight cystitis. Tubercle bacilli persisted in the urine of 8 cases, in 7 of which the cystitis was unchanged. The remaining person showed some worsening of the slight bladder disease.

In 2 of the 10 patients the remaining kidney became tuberculous during the period of observation. One of these patients died of uræmia after refusing any form of treatment. These results are summarized in Table II.

S=Streptomycin C=Control

The number showing conversion of the urine seems to be significant in this group of streptomycin-treated patients, but the numbers are too small to comment on protection of the remaining kidney. Improvement of cystitis can also be expected in the majority of cases, although it appears that in patients with a greatly reduced bladder capacity and severe cystitis, one must be prepared for a marked aggravation of micturition which may persist after the cessation of streptomycin. A graph showing the diurnal and nocturnal frequency of micturition in the 2 patients who had contracture of the bladder rose sharply soon after the start of treatment, and the following case is worthy of note.

M. A., female, aged 24. *Group* 2

This girl had a right nephro-ureterectomy in Robroyston Hospital in December 1947. She was readmitted at the end of 1948, because of a persistently positive bladder urine.

Examination in January 1949 showed a bladder capacity of 14 oz. and a shallow elongated ulcer between the ureteric orifices. The urine from the left kidney was negative and normal pyelograms were obtained. She was placed in Group 2 and she became a control case.

Repeated examinations showed that by August the bladder capacity had been reduced to 8 oz. but by October some improvement was noted. On October 14, 1949, a course of streptomycin was started outwith the controlled investigation. Almost immediately, frequency of micturition was greatly intensified, occurring at 15 to 20 minute intervals. Both vestibular nerves were damaged after one month and the drug was stopped after two months. One month after the cessation of treatment, the patient felt well and was able to walk during the day without unsteadiness, compensating for vestibular dysfunction by vision. Urination was necessary every 15 minutes but the bladder urine did not contain tubercle bacilli. Urographic examination showed a contracted bladder and consequent back pressure dilatation in the ureter and renal pelvis of the remaining kidney (Fig. 5). Transplantation of the ureter into the pelvic colon was therefore carried out.

In this case, streptomycin was followed by severe contracture of the bladder and gross vestibular damage. On the other hand, the bladder urine did not contain tubercle bacilli.

FIG. 5 (*Case M. A.*).—Retrograde cystogram made two years and three months after a right nephro-ureterectomy and one month after completing a course of streptomycin treatment. The pyelo-ureterogram, obtained as a result of regurgitation of the radio-opaque fluid from the bladder, shows moderate dilatation. This is due to back pressure, the kidney being uninfected.

GROUP 3.—Patients in this group suffered from bilateral renal tuberculosis with the disesae more advanced on one side indicating, in our opinion, removal of that kidney. The operation was the same in all cases being that of nephrectomy without ureterectomy. 12 patients, 5 females and 7 males, were placed in this category and 6 were given streptomycin therapy after the operative procedure.

Streptomycin cases.—Consideration of the 6 patients who had a course of streptomycin showed that conversion of the bladder urine from positive to negative for tubercle bacilli occurred in 3 instances and conversion of the solitary remaining kidney urine in 4 instances. The 3 negative bladder results have persisted for eight, nine, and ten months respectively, while the patient with the negative kidney and positive bladder urines has been examined at one, two and four monthly intervals since the cessation of the treatment.

Originally the remaining kidney lesion was not obvious pyelographically in 3 instances, was visible as a small lesion in 2 and as a moderate lesion in the remaining 1. Follow-up renal examinations showed that there was no alteration in the 3 normal looking kidneys, that a small lesion had apparently disappeared in 1, a small lesion was unchanged in 1 and that the moderate lesion had shown deterioration.

All 6 patients had visible cystitis before treatment and improvement after treatment was noted in 5 while the sixth was unchanged. The improvement amounted to a clearing of the bladder mucosa in 1 with previous slight cystitis, to slight from moderate cystitis in 4, while the 1 patient with severe bladder involvement showed no change after treatment.

Control cases.—In the 6 patients who did not have streptomycin there was no example of urine conversion. In all cases the bladder and remaining kidney urine specimens showed tubercle bacilli for a period varying from four to eight months.

At the beginning of the control period the remaining kidney lesions were visible by pyelography in 4 instances but could not be seen in 2. The lesions were all small and on re-examination it was found that in 2 cases an initial small focus had deteriorated and in 1 case where no lesion had been visible there now appeared a filling defect in the upper pole of the kidney. No alteration was noticeable in the remaining 3 patients.

Cystitis was classified as slight in 4 patients, moderate in 1 and severe in 1, before the observation period started. In the most recent examination, four to eight months afterwards, the cystitis was found to be worse in 3, unchanged in 2 and slightly improved in 1. These results are summarized in Table III.

S=Streptomycin C=Control

Conversion of the urine in this group is also significant, although it probably depends to a great extent on the severity of the remaining kidney lesion and to a lesser extent on the degree of cystitis. What seems to be important is the fact that the conversions of the urine have persisted up to the present, although a prolonged follow-up will be necessary. It should be noted, however, that the conversion occurred in patients with a small lesion in the remaining kidney. In one case with a moderate kidney focus the disease worsened and the separate urinary specimens contained tubercle bacilli.

Again the findings indicate that an improvement in the cystitis can be expected in the great majority of patients. The disappearance of an obvious kidney focus seems an unlikely occurrence.

M. O., female, aged 22. *Group* 3

This patient had her left kidney removed in November 1948 after a previous examination had shown bilateral renal tuberculosis with the disease more marked on the left side. Excretion pyelography demonstrated the right kidney as a series of dilated calyces with a distended pelvis. On retrograde pyelography the calyces, pelvis and ureter were seen to be dilated. These changes were considered to be due to back pressure. The bladder capacity was under 7 oz. and the cystitis was noted as severe.

She also suffered from chronic bilateral pulmonary tuberculosis and investigation before streptomycin showed almost total destruction of the epiglottis with swelling of the right artytenoid and ulceration of the left ventricular band. These conditions were symptom-free and were considered to be compatible with a tuberculous process of long duration.

Streptomycin was started on December 6, 1948, and stopped on March 6, 1949.

Re-examinations were carried out one, five and seven months after treatment. Catheterization of the right ureter was never possible after the initial examination but on these examinations the bladder urine was persistently positive for tubercle bacilli. Excretion pyelography showed a worsening of the kidney lesion although there was slight improvement in the cystitis.

Streptomycin, in this case, did not prevent deterioration of a kidney lesion and it did not convert the urine. There was, however, slight improvement in the cystitis, marked improvement in the general condition and disappearance of the laryngeal ulceration.

W. McM., male, aged 19. *Groups* 1 *and* 3

Admitted with a left epididymitis and no urological symptoms, this boy was found to have a tubercle

positive urine. Investigation showed that he had a filling defect in the upper calyx of the left kidney, the urine from which contained tubercle bacilli. There was no cystitis and the patient was placed in Group 1. He was designated as a control case.

Six months later there was slight cystitis and the urine specimens from the bladder, right and left kidneys were all positive. As his primary control period was finished and he now qualified as a Group 3 case, his name was again submitted for consideration. Again he was a control case. Nephrectomy was carried out on the left side. Four months later, at the end of the control period, the bladder and right kidney urines still contained tubercle bacilli and the cystitis showed some worsening.

This patient is now having streptomycin and para-aminosalicylic acid but it is too early to assess the result.

This is probably a case in which many would give streptomycin while careful watch was kept on the urological condition, ready to step in at any time and remove the left kidney.

GROUP 4.—Six patients, 5 males and 1 female, were assessed as complying with the standards of Group 4. This group contained those patients who developed disease in the remaining kidney after a previous nephrectomy for renal tuberculosis. 4 of these patients received streptomycin.

Streptomycin cases.—The 4 patients who were treated with streptomycin all had severe cystitis and advanced disease of the surviving kidney. One man developed uræmia a fortnight after the onset of treatment and died within a week. In 2 of the remaining 3, frequency of micturition was aggravated during the course of streptomycin, being sufficiently severe in one to necessitate transplantation of the ureter, while in the third patient there was some improvement in the frequency of micturition.

In only 1 of the 3 cases has the urine shown conversion. That case, in which the ureter was transplanted, has remained negative up to the present, two months since the cessation of streptomycin. The specimen of urine from the divided ureter at operation failed to show tubercle bacilli.

The pyelographic appearances in all 3 have remained unchanged.

Control cases.—The 2 men who did not have streptomycin elected to discharge themselves from hospital. Both had ulcerocavernous disease of the single kidney with associated severe cystitis. Out-patient follow-up, many months after the first examination, showed marked deterioration of the renal and bladder conditions and the urine still contained numerous tubercle bacilli. These results are summarized in Table IV.

S=Streptomycin C=Control

Tuberculosis of the solitary remaining kidney was advanced in the cases under review and apart from slight improvement in the cystitis of one treated by streptomycin no changes were noteworthy. Aggravation of an already severe cystitis was again noted.

It appears that in this type of case, no lasting improvement can be expected with streptomycin and taking into account possible toxic effects, many may consider it inadvisable to give the drug.

GROUP 5.—At the beginning of the investigation it was decided to subdivide Group 5 into two, 5A and 5B. Patients suitable for 5A had major bilateral renal lesions for which no active measures were considered possible, while those eligible for 5B had small bilateral lesions of a minimal nature but lesions which could be seen on pyelograms. In that way patients with tubercle bacilluria were excluded. The number of patients who came under observation with bilateral minimal disease was very small and later the subdivision was abandoned. For interest, however, 3 patients in this subdivision will be included in the results.

The number admitted to Group 5 more than four months ago was 16. 8 of these patients, 3 female and 5 males, were given a course of streptomycin and one of the females came under the section of small bilateral lesions. The results are somewhat difficult to describe in detail, as in many instances catheterization of the ureters was impossible on account of the advanced bladder changes, and good excretory pyelograms were difficult to obtain because of the renal destruction.

Streptomycin cases.—2 of the 8 cases treated by streptomycin died before the urological condition was reinvestigated. One death was due to uræmia and occurred within three weeks of the start of the drug. It is impossible to blame the drug for precipitating death in this man with advanced renal disease as he had been in hospital for a long period with spinal tuberculosis and his condition had remained satisfactory until just before the streptomycin

was started. Despite signs of deterioration it was decided to give him the possible benefits of treatment. The other death occurred in a man with advanced renal disease and his death was considered to be due to an intracranial tuberculoma with associated meningitis. This lesion manifested itself two weeks after the cessation of his treatment before follow-up examination was due and unfortunately a post-mortem examination was refused. The histological examination of the kidneys after 90 grammes of streptomycin might have been of value.

Excluding the 2 deaths and the 1 patient with small bilateral lesions, 5 cases remain to be considered. Of these 5, 4 had advanced bilateral ulcerocavernous disease of the kidneys and re-examination up to six months after the end of the course did not reveal any obvious changes. The remaining patient, a female, had been under observation for some months before being admitted to the investigation. She suffered from a slight cystitis and had cavitation in the lower segment of the right kidney and a moth-eaten appearance of the upper calyx on the left side. One month after treatment, the bladder and left kidney urines were still positive for tubercle bacilli but three months afterwards all separate specimens were negative. The negative results were all confirmed at four and five monthly intervals after the streptomycin and the bladder were found to be normal.

The patient in Group 5B was a woman who on examination was found to have a dull lustreless bladder mucosa with a bladder capacity of 15 oz. Retrograde pyelography showed small lesions in both kidneys and the bladder, right and left kidney specimens all contained tubercle bacilli. One month after streptomycin, the bladder capacity was 20 oz. and all separate urinary specimens were negative. The examination was repeated four months later when again all the specimens proved negative.

Control cases.—Control cases in this group numbered 6 with major lesions and 2 with small lesions. Of the 6 with advanced disease, 2 died within a short time of the start of the investigation, 1 of uræmia and the other of cerebral hæmorrhage. The remaining 4 all had severe cystitis with advanced renal disease. Re-examination four months to one year after admission showed that the renal disease was unchanged, the cystitis not improved and the urine still contained abundant tubercle bacilli.

The 2 patients with minor lesions were both re-examined up to a year after the start of the period of observation. The bladder mucosa, normal when first seen, was still free of disease at the end of a year. The retrograde pyelograms of one showed no alteration but several kidney specimens were all found to contain tubercle bacilli, while the retrograde pyelograms of the other showed lesions in both kidneys which had deteriorated and all separate specimens of urine were still positive to tubercle bacilli. These results are summarized in Tables V, VI and VII.

S=Streptomycin C=Control

Again in this type of case, with obvious bilateral renal tuberculosis, the prognosis does not appear to have altered with the introduction of streptomycin. One case, which has been mentioned before, is worth demonstrating. The outlook in this girl has improved with streptomycin but continued observation is still necessary. It is noteworthy that the bilateral renal lesions in this patient were less advanced than those of the remaining patients in Group 5A.

E. McG., female, aged 21. *Group 5a.*

While under treatment for pleurisy in another hospital, renal tuberculosis was found to be present in January 1949. At that time cavitation was present in the lower segment of the right kidney but

FIG. 6 (*Case E. McG.*).—Bilateral retrograde pyelogram showing an advanced lesion in the right kidney and a focus connecting with the upper calyces of the left.

FIG. 7 (*Case E. McG.*).—Bilateral retrograde pyelogram two and a half months after completion of treatment. The diseased area in the lower pole of the right kidney is shut off.

FIG. 8 (*Case E. McG.*).—Bilateral retrograde pyelogram three months later. The communication with the lower pole is again patent.

specimens of urine from both kidneys were found on animal inoculation to contain tubercle bacilli. She was transferred to Robroyston Hospital at the end of May 1949. Examination there showed a slight degree of cystitis with bladder discomfort occurring with a content of 14 oz. Excretion and retrograde pyelography showed clubbing of all the calyces on the right side with constriction of the uretero-pelvic junction. On the left side the upper segment had a moth-eaten appearance with a constriction at its opening into the pelvis (Fig. 6). The X-ray and bacteriological findings confirmed a bilateral renal lesion but, in our opinion, there was no indication for removal of one kidney.

A course of streptomycin was started on June 24 and completed on September 21, 1949. One month after treatment, cystoscopy was repeated. The vesical mucosa now appeared normal and the bladder and separate kidney specimens were still positive for tubercle bacilli. Retrograde pyelograms were unchanged. Repeat urological examinations were carried out at two, four and six monthly intervals. The bladder capacity was then 22 oz. and the mucosa normal. Specimens of urine from the bladder, right and left kidneys were all negative. Retrograde pyelography showed that the lower segment on the right side was partly shut off in the earlier examinations but in the latest picture the lower segment was again open. On the left side there was an infundibular constriction to the upper calyx which had a moth-eaten appearance (Figs. 7 and 8).

This case has benefited from streptomycin but the observation period is too short to reach a definite conclusion. Vestibular function was unimpaired.

In patients with small bilateral lesions the outlook may be improved with streptomycin therapy. The following case seems to be an example of this.

Mrs. A. B., female, aged 32. *Group* 5*b*.

Examined in March 1949, she was found to have bilateral renal tuberculosis with a moth-eaten appearance of the upper calyces on the right side and clubbing of the terminal calyces of the upper group on the left side. The whole bladder mucosa was dull and lustreless with a capacity of 15 oz. without anæsthesia.

She was placed in Group 5B and streptomycin was started on June 24 and stopped on September 21.

Examinations one and four months after streptomycin demonstrated that the bladder capacity was over 20 oz. and all separate urinary specimens were negative for tubercle bacilli. Retrograde pyelograms were still abnormal but showed an improvement. Her general condition was greatly improved but there was marked vestibular dysfunction.

Summing up the results in Group 5, it is obvious that streptomycin cannot be expected to heal advanced lesions in a structure so highly organized as renal tissue. It seems reasonable to suggest that where lesions are so small that they could be replaced by fibrous tissue, as in Group 5B, streptomycin is not only justifiable but imperative when one remembers that this is a bilateral condition. This would also apply to patients with tubercle bacilluria.

Conclusions

The mode of this investigation was planned with the deliberate intention of eliciting all possible information of an objective character about the effect of streptomycin on the urinary tract infected by tuberculosis. As was mentioned at the outset of our communication the investigation continues and is likely to do so over a period of years. We consider, however, that as a result of our 15 months' experience, the following preliminary observations can be offered.

The treatment has no effect on an established caseocavernous renal lesion. This is not surprising for in spite of the high elimination of streptomycin by the kidney, a blood-borne therapeutic agent must, for the most part, be excluded from such an avascular focus. By encouraging fibrosis and consequent constriction there is a possibility that the focus, though itself remaining active, may become shut off. A regression of the constriction, however, can occur. Streptomycin therapy cannot therefore be recommended to supplant surgery and in clinical unilateral renal tuberculosis the diseased kidney should be removed.

We do not advise its automatic employment in all cases unsuitable for surgery. Thus when there is an advanced bilateral renal lesion or an advanced lesion in a solitary kidney, no improvement in the kidney lesion can be anticipated and vesical contracture may be accelerated.

From our experience with Group 2 cases, we consider streptomycin may prove beneficial as an additional therapeutic measure, possibly before as well as after surgery. Accepting Medlar's claim that in renal tuberculosis both kidneys at the outset are involved by minimal lesions, then after nephrectomy for a unilateral clinical lesion, streptomycin should diminish the risk of activation and development of the disease in the apparently healthy kidney. This statement is given with reservation, however, for in Group 1 cases the contralateral kidney became tubercle positive in 3 out of 7 treated cases whilst this occurred in only 2 out of the 8 controls.

Streptomycin does have a definite beneficial effect on secondary tuberculous cystitis but this would appear to be relative to the presence and degree of disease in the upper urinary tract. Thus in our Group 2 cases, that is those with a unilateral renal lesion who have been nephrectomized, cystitis has cleared and the urine has become tubercle negative in an appreciably larger number of streptomycin treated cases than has occurred with the controls.

With group 5 cases, however, consisting chiefly of patients with well-established bilateral

disease, no beneficial effect on the bladder resulted. In the few cases of Group 5 in whom the bilateral lesions were minimal, the effect of streptomycin on the bladder has been good.

It will be evident from the results we have so far obtained in this controlled trial, that the administration of streptomycin to those suffering from urinary tuberculosis is not an alternative to prolonged sanatorium care or to nephrectomy when the renal lesion is a unilateral one. Employed as an additional therapeutic measure, however, streptomycin may enhance a patient's chances of recovery.

ACKNOWLEDGMENT

The authors are indebted to the Tuberculosis Research Unit of the Medical Research Council for making this research possible and for supplying all the streptomycin required. They acknowledge with gratitude the help received from Dr. Marc Daniels and Dr. P. D'Arcy Hart in the planning of the investigation and in the assessment of the results.

The President said that in tuberculosis of the urinary tract the assessment of the effects of treatment and the comparison of one method with another was extremely difficult because the cases which one attempted to control were encumbered by so many variable factors.

He was a little disturbed concerning the suggestion that the intravenous pyelogram might not be good enough for diagnostic purposes. Most members had had the privilege of working in institutions outside their main teaching hospitals, and in some the radiological work was not of the standard found in the large general hospitals. Thus intravenous pyelography might sometimes prove unsatisfactory.

However, retrograde pyelography was not necessary in every case, and he deprecated the impression that it was necessary to make a retrograde pyelogram as a routine. The stereoscopic X-ray method with intravenous pyelography was worth while in cases in which the pyelograms were difficult to interpret.

One point of fundamental importance in this work was the relationship of the renal lesion to the general condition of the patient. He believed that cases needed in the first instance to be segregated into two big groups. The first group would consist of patients who had advanced, established, and progressive tuberculous lesions somewhere else—in other words, the sanatorium population—and who in the course of their illness developed renal lesions. These patients had a renal lesion as an incident in an infection which was likely to end fatally whatever was done for them.

The other group was that familiar to the ordinary out-patient department in the general hospital. These were people who came up complaining of increased frequency of micturition, and in whom tuberculous lesions of the urinary tract without gross disease elsewhere were discovered. Such patients might be expected to get perfectly well after suitable treatment. It was essential to clear the ground at the beginning by dividing the patients into those two groups.

With regard to the openers' statement that their patients had had the kidney removed but not the ureter, he asked why the more complete operation was not favoured, and how many such patients developed breaking down wounds subsequently.

He also asked in how many cases of patients in whom a tuberculous infection had returned after streptomycin treatment, the organisms had become resistant to streptomycin, and in how many the organisms were still sensitive.

Mr. E. W. Riches said that he considered the following cases were suitable for streptomycin:—

(1) Bilateral cases after nephrectomy on the worse side. The fact that tubercle bacilli had already been discovered on the relatively good side was not always a contra-indication to operation.

(2) Residual bladder lesions after nephrectomy.

(3) Cases with bladder lesions and a positive urine, but with no demonstrable renal lesion, or cases in which there was a doubt about the side of the renal lesion.

He asked about the post-operative prophylactic use of streptomycin in unilateral cases. If given it should be in a full course.

He had treated 16 cases, eleven of whom had been treated about a year or more ago. 10 of these were alive; the eleventh had miliary tuberculosis. In all these 10 cases there had been symptomatic improvement, but repeated search often revealed tubercle bacilli. A boy of 15 with a bilateral infection underwent nephro-ureterectomy and was given 50 grammes of streptomycin and 50 c.c. of moogrol. After six months twenty-four-hour specimens of his urine were taken; the first four specimens were all negative, but the fifth was positive.

Guinea-pig inoculation and culture entailed a lot of extra work for the bacteriologist but it was very necessary. It could not be said that a case was negative on the smear from a twenty-four-hour specimen alone.

He had been interested in the question of the contraction of the bladder and the ureter and whether it would improve or worsen on streptomycin. In a man with bilateral disease, left nephro-ureterectomy was done two years ago and he was given 90 grammes of streptomycin. The pyelogram taken eighteen months later showed the kidney to be rather more dilated and the ureter rather more tortuous, while the bladder was slightly more contracted. He was getting a back pressure kidney and he ought to have a transplantation. He was unwilling to come up because he was doing a full day's work as a motor mechanic. He suffered from the inconvenience of having to get up twice or three times in the night, but otherwise he was able to lead a normal life.

There had been one or two cases in which bladder capacity had increased. In one case after surgical treatment and streptomycin the bladder capacity for some time was only 5 oz., but had now increased to 16 oz., although the patient still had a positive urine.

There was one other point which must not be neglected, namely, the effect of streptomycin on the

vestibular apparatus. After 50 grammes, many patients got vestibular symptoms, and they were very miserable, being giddy in the daytime, and totally unable to stand up in the dark. Eventually they improved but he did not think they got well. He thought they must not lose sight of the occurrence of this damage, because unless they could be sure of some definite improvement in the renal tuberculosis by the use of this drug, it was in many cases a contra-indication to its use.

Mr. M. F. Nicholls said that he had the advantage of being urological surgeon to a large orthopædic hospital, and many of the cases he had to deal with came in the second group to which the President had referred. Renal tuberculosis came much more frequently from bone and joint tuberculosis than many people seemed to realize. Patients seemed to develop overt urinary tubercle when the bone and joint tubercle was on the way to healing. He had removed several kidneys after a full course of streptomycin, and the renal disease seemed to be unaffected by the drug.

He went on to describe one particular case. This was the case of a man whose spinal tuberculosis had virtually healed. He then developed frequency, and on cystoscopy was shown to have a minimal tuberculous ulceration of the bladder. The left ureteric orifice was diseased and would not admit a catheter. The right ureter was catheterized and proved tubercle-free. Owing to a technical fault in the X-ray installation, the ascending pyelogram could not be done. A course of streptomycin was started, and in a fortnight the bladder on further cystoscopy appeared entirely normal. Four months later, after the patient had had 50 grammes of streptomycin, he removed the left kidney which showed numerous pinhead lesions of the cortex, none of which encroached on the kidney pelvis or calyces which were normal. Histologically the tuberculosis was shown to be active in spite of the streptomycin.

Mr. D. S. Poole-Wilson said he had carried out streptomycin therapy on 14 cases. In 10 the treatment had been completed for some time and a tentative assessment of the results could be made. The dosage of streptomycin had been 0·5 gramme twelve-hourly for 120 days. As far as could be ascertained all the patients were free from active tuberculosis outside the urinary or genital tracts.

The patients fell into six categories:

(1) Bilateral renal tuberculosis with minimal but proven lesions in each kidney.

(2) Bilateral renal tuberculosis in which a major lesion on one side had been treated by nephro-ureterectomy and a small lesion is present in the remaining kidney.

(3) Unilateral renal tuberculosis—small lesions.

(4) Renal tuberculosis appearing in the remaining kidney after the other kidney and ureter had been removed for tuberculosis.

(5) Chronic tuberculous ulceration or cystitis persisting after removal of an infected kidney and ureter and in whom the remaining kidney appears healthy.

In connexion with this and the previous group the importance of nephro-ureterectomy in the treatment of renal tuberculosis was stressed. If a nephrectomy only is carried out a tuberculous ureteric stump may be left in situ and act as a focus for continued infection of the bladder. The presence of tubercle bacilli in the urine of such patients does not therefore necessarily indicate infection of the remaining kidney. In such cases removal of the infected ureteric stump may effect considerable improvement.

(6) Tuberculous sinus formation following operations on tuberculous kidneys.

The single patient in this group was a young boy, whose right kidney was removed on account of gross tuberculous infection. His condition did not warrant full removal of the ureter, which was as thick as a little finger. The wound subsequently broke down completely and refused to heal. Eventually the remainder of the ureter was removed and streptomycin therapy commenced. Subsequent healing was rapid.

In assessing the effects of streptomycin therapy it was noted that whereas tubercle bacilli were present in all the urines prior to treatment, at the completion of the course 6 were free of tubercle bacilli and in 4 the organism still remained present. After a matter of months, 2 of the 6 tubercle-free patients reverted and again showed tubercle bacilli in their urine.

Treatment had finally to be stopped in 1 patient owing to a severe urticarial reaction.

Vestibular symptoms were fairly severe. Some of the patients had a rather miserable time during the third and fourth months of treatment. During the early stages of treatment the patients were allowed out for short walks. By the third month some felt that they were not safe in going out alone and could not walk steadily in the dark; if blindfolded they could not maintain their standing balance.

Of the 9 cases receiving a full course of treatment, 5 showed marked clinical improvement. In 3 there was no appreciable change. From this small series it would appear that in about 40 to 50% of cases some clinical improvement will occur following streptomycin therapy. How long the improvement will be maintained is not known and some patients have paid a fairly heavy price in dizziness for the amelioration of their renal and vesical lesions.

Mr. Hugh Donovan said that he thought the paper to be a most important one, because it was an accurate and painstaking study of the effect of 1 gramme of streptomycin given daily over three months and because it showed that this dosage was quite inadequate. A report from the Veterans' Bureau (1949) had described some very encouraging results from 2 grammes of streptomycin given daily for four months. The speaker had found that 3·2 grammes of streptomycin was too toxic, and following the principle of naval gunnery he estimated that 2 grammes a day would probably prove to be the correct dose. He drew attention to a recent address by Dr. Geddes, given in Birmingham, in which the effect of simultaneous administration of P.A.S. was described. It seemed that this drug prevented the tubercle bacilli becoming resistant to streptomycin. Mr. Donovan concluded by pointing out that it was generally held to be dangerous to do an ascending pyelogram on a tuberculous kidney, and asked whether this might not have been responsible for some of the relapses in Mr. Jacobs' series.

116021 J. E.	TB vasostomy wound	1 unit	1/2 b.d.	60	Yes 32 units	None	None	Healed in seven weeks
99599 M. W.	TB ulcer vault of vagina	—	1/2 b.d.	70 (including local)	None	Mild Recovery	None	Healed in twelve weeks

Group 1 (7 cases) consisted of post-operative wound infections (Table II). He showed a number of slides illustrating the beneficial effect of streptomycin in these cases. Some wounds were excised and sutured under an "umbrella" of streptomycin. Primary union occurred. In one case skin grafts were applied. The grafts took and consolidated while streptomycin controlled the infection. Epithelialization continued after stopping streptomycin.

Group 2 (5 cases) were unoperated cases. Two early unilateral renal cases appeared to benefit from streptomycin.

Group 3 (14 cases) were cases with cystitis persisting after nephrectomy. A beneficial effect was noted in 10 cases.

Group 4 (4 cases) consisted of cases complicated with open pulmonary tuberculosis. One of these cases was refused treatment because the chest lesion was of the type which was known to respond unfavourably to streptomycin.

In this series of 28 cases the dosage of streptomycin had ranged from 10–120 grammes (Table III).

TABLE III.—STREPTOMYCIN IN GENITO-URINARY TUBERCULOSIS

Total Dosage of Streptomycin Used

Dosage in grammes	Number of cases
10	1
35	1
42	1
60	24
120	1

The first case (cystitis persisting after nephro-ureterectomy) treated with streptomycin was given only 10 grammes. The effect was satisfactory.

Of the complications (Table IV), hæmaturia occurred in two cases during treatment and was also noted later in a third case. A resistant strain of tubercle bacillus appeared in 4 cases—in 1 case in the fifth week, in 2 cases in the seventh week, and in the remaining case in the ninth week.

TABLE IV.—STREPTOMYCIN IN GENITO-URINARY TUBERCULOSIS

Complications Noted During Treatment of 28 Cases

Complications	No. of cases during treatment	No. of cases one year after treatment	Remarks

Deafness	nil	nil	
Myalgia	1	nil	Improved
Hæmaturia	2	2	
Renal failure	nil	1	Died
Pneumonia	nil	1	Died
Resistant strains of tubercle bacilli	4	nil	

Recently P.A.S. had been used. It was hoped that the synergic effect of antibiotics and chemotherapy might prove of value in genito-urinary tuberculosis.

Mr. David Band said that each of the five groups of clinical cases selected for streptomycin therapy had been covered by a comparable series of controls classified into similar groups, in which streptomycin was not used. The results in this investigation had been presented objectively and had been tabulated. It seemed that it was a fair challenge to invite Mr. Jacobs to say whether he thought streptomycin could replace the sanatorium as an essential adjuvant to the surgery of urogenital tuberculosis. Tuberculosis was a social problem, and would not be overcome by surgery, nor by the employment of streptomycin or any other antibiotic. It was a disease which had its beginning in childhood largely as a result of inadequate housing and faulty social conditions.

Mr. Walter M. Borthwick, in reply, said that the President had suggested that X-ray work in sanatoria was not quite up to standard. The sanatorium at which he worked accommodated almost 600 patients with tuberculosis and the quality of the X-ray work done by their radiological staff had reached a very high standard.

With tuberculous patients it was imperative that the pulmonary and non-pulmonary cases should not be in one unit and the number of renal cases outwith the genito-urinary unit, which was situated in the non-pulmonary section of the hospital, had been negligible; he could think of only one case at present which came into that category.

He agreed with what Mr. Nicholls had said about renal tuberculosis being frequently present in patients with bone and joint lesions. He saw a number of such cases, and, at present, out of 40 patients with renal tuberculosis, only 1 suffered from open pulmonary tuberculosis.

It was impossible to tell by intravenous pyelography every time there was a lesion in the kidney. Many of the cases were very clear, but there were others which required retrograde pyelography to demonstrate a small focus. One authority had mentioned epididymitis as a possible symptom of renal tuberculosis, and often in these cases the renal lesion was small and difficult to localize. It was in the obscure case with slight indications that they wanted to find out whether streptomycin was of benefit.

In his experience, most of the sinuses following nephro-ureterectomy were related to the abdominal wound and he wondered whether the removal of both kidney and ureter was not responsible for more complications.

Mr. Band had remarked that this was a controlled investigation. They had tried to treat the controlled case exactly the same as the one treated with streptomycin apart from the drug. The rise in the resistance was very important and he heartily agreed with one of the speakers who had mentioned a case of advanced pulmonary disease with a hopeless prognosis. They would also withhold streptomycin in that case. There was no case in this series with cavitation in the lungs.

As to the dangers of streptomycin, his patients were in bed for at least three months. He was surprised when Mr. Riches spoke of a definite improvement of vestibular damage within a year as he did not know there could be a recovery. If these patients were examined he thought it would be ound that unsteadiness did persist.

This investigation was undertaken under very strict rules: 90 grammes was the maximum dose to be given and no allowance was made for repeating the course. There was freedom of action after the observation period was over. Their dose of PAS was higher than had been mentioned in the discussion. They were giving 12 grammes a day but it was too early to give results.

Mr. Arthur Jacobs, also in reply, said that for routine investigation of the urinary tract in tuberculosis they were satisfied with intravenous pyelography follov ed by ureteric catheterization and the collection of urine from the apparently healthy kidney to confir.n that it was uninfected. But for the purpose of this investigation it had been felt that retrograde pyelograms would be required to portray changes taking place in a renal lesion. The employment of both methods in every case had confirmed this opinion, particularly for the delineation of the smaller foci. Contrary to what had been suggested by Professor Wells and to what is frequently stated, they were unaware of any evil sequelæ following retrograde pyelography in renal tuberculosis. He considered it was not without significance that not one of the discussants had attempted to demonstrate to the Meeting the progress of a lesion under treatment, by showing excretory pyelograms.

With regard to the question of nephro-ureterectomy rather than nephrectomy being the operation of choice, Mr. Jacobs indicated that the experience at Robroyston had been that nephrectomy alone was followed by a lower incidence of post-operative sinus formation than nephro-ureterectomy and that removing the complete ureter did not ensure resolution of a secondary cystitis. They had been rather disappointed with the effect of streptomycin on the bladder for although it might hasten a resolution of the secondary cystitis and even heal an area of ulceration the fibrosis associated with the healing process could result in a progressive contracture. Once this occurred it was irreversible and several cases in the series had, in consequence, required ureteric transplantation.

Concerning dosage it had been suggested that a larger amount than a gramme a day might be given and that the course should be longer than ninety days as in some of the trials reported from the U.S.A. He had, however, noticed in the more recent American literature a tendency to diminish the amounts, approximately to that used at Robroyston.

Finally in answer to Mr. Band he stated that in his opinion a sanatorium régime combined with nephrectomy when the disease was unilateral was still the most important method of treatment for renal tuberculosis. Streptomycin could be helpful but it had its limitations and might be dangerous. The equivocal results of the drug when given for renal tuberculosis were the justification for continuing the investigation as a controlled one and not giving streptomycin indiscriminately to every sufferer with a tubercle-positive urine. He hoped by this method that it would finally be possible to select the patients likely to benefit from the treatment and eliminate those whose condition might be worsened.

The President said that it was wise to avoid retrograde catheterization if possible, because of the undoubted, though admittedly small, risk of spreading infection. Everyone knew that if one took a patient with a septic infection and did a cystoscopy, a rigor might follow, and one visualized organisms in the blood stream with a constitutional disturbance. The same notion had to be entertained in the case of tuberculous infections.

When an intravenous pyelogram was necessary to clear up some doubtful point then the best moment to make it was when the patient walked into hospital. When patients had been in bed for a considerable period difficulties due to gas were greatly increased. Such inevitable difficulties were especially likely to arise in patients suffering from tuberculosis and confined to bed. He had himself had the privilege of working for many years in an institution devoted to the treatment of non-pulmonary tuberculosis and appreciated to the full the peculiar difficulties in this type of case.

The Renal Circulation [1]

By K. J. FRANKLIN, D.M., D.Sc., F.R.C.P.

*Department of Physiology, St. Bartholomew's Hospital Medical College, London, E.C.*1

THIS Address was to have been a joint one by Professor Trueta and myself, but the calls which his new duties made upon his time prevented him—to my great regret—from participating[2]. I acknowledge my indebtedness to him and to my other colleagues in renal research, while stressing that they are not necessarily involved in the interpretations or views which I advance. My survey is shorter and less complete than I wish; also, according to the nature of scientific reviews, it is doubtless a mixture of elements which are lasting and of others which increase in knowledge will show to be ephemeral or incorrect. It may, however, serve some useful purpose as an unbiased interim account of a subject of physiological interest and clinical importance.

In the light of recent biochemical research upon what Schoenheimer (1946) so happily styled "the dynamic state of body constituents", the meaning of the word "circulation" needs to be extended so as to cover both the extravascular and the intravascular movements of water and solutes. The volume which so moves in and out each day is of the vast order of 7,000 litres (calculated from data in Flexner *et al.*, 1942), while the glomerular filtrate is about 180 litres and the output of urine about 1·5 litres. So the renal fluid excursion, contrary to what was generally thought but a few years ago (*see* e.g., Smith, 1943) is in fact *relatively* small. I mention this at the outset in order that the renal *blood* circulation, with which I am in the main to deal, may be envisaged in its proper relation to the total fluid movement of the body.

ONTOGENY

The physiological range is from conception to death, and we need to know what changes occur within that range in the renal vascular system and circulation, especially those of the human subject. The pronephric stage is virtually non-existent in mammals, nor is much known about the succeeding mesonephric one, but there is more information about the intra-uterine part of the metanephric stage which begins, before the mesonephric is over, at a fœtal age (in the human subject) of 4 to 5 weeks. The basal or juxtamedullary glomeruli, which are the first to develop and also the first (Morison, 1926) to be vascularized, begin to appear at 6 to 7 weeks, and are fairly fully formed at 10 weeks[3], while (Hewer, 1925) the glomerular basement membrane is well developed by 12 weeks. Cortical glomeruli are added in successive layers on the outside until the fœtus or newborn child has attained a weight of 4·5 to 5·5 lb. (Potter and Thierstein, 1943) and, presumably in correspondence with this, one can see an occasional large vessel in the cortex and considerable subcapsular vascularity[3]; the vascular loops of the outermost glomeruli are not so well-developed as those of the basal ones (Clara, 1936), and at times degenerate units are present in the subcapsular layer (Gruber; Peter, 1909; Peter *et al.*, 1927). In the fœtus the basal glomeruli are larger than the cortical ones—Külz (1899) gave the respective diameters as 138 μ and 99 μ (adult 240 μ); the glomerular tuft is completely covered by high cuboidal or columnar epithelium. Further anatomical details are that the cortex is narrow relative to the medulla, with the glomeruli close to one another in all three dimensions, and that (Daniel, 1947), in sections of the earlier stages, red blood corpuscles are much more numerous in the basal glomeruli and in the medullary vessels than they are in the cortex in general. The renal innervation in various mammalian fœtuses, including a 21 weeks' human one, is described by De Muylder (1948), who also gives references to earlier work. In the human subject, there is a very rich, mainly but not exclusively non-myelinated, supply reaching the kidney along the renal pedicle and the ureter and distributed, except for a few fibres to supporting tissue, essentially to blood vessels. The peri-arterial plexus supplies, *inter alia*, the afferent and efferent glomerular vessels and is in close relation to the macula densa; it misses the glomerular capillaries.

[1] Slightly abridged; to be integrated with Franklin (1949).

[2] What, *inter alia*, he might have added can be gauged from the review (Trueta, 1950) which appeared while this account was going to the Press.

[3] According to evidence provided by sections in the Department of Physiology, St. Bartholomew's Hospital Medical College.

The perivenous plexus, in the fœtus, is associated with ? chemoceptive end-organs lying, covered with endothelium, out in the renal vein blood stream, and with ? pressoceptive end-organs which do not so project[1].

The blood pressure in the mature human fœtus *in utero* has only once, so far as I know, been measured and in that instance it was 68 mm.Hg (Haselhorst, 1929). Of hormonal and nervous influences affecting the human pre-natal renal circulation I have no direct evidence, but Govan's (1949) findings in asphyxia neonatorum suggest that, in shock, such blood supply as there is to the kidney is preferentially distributed to the medulla. With regard to urine formation *in utero*, Gersh (1937), on the basis of findings in lower animals, thought that tubular excretory function may begin at 9 weeks in the human fœtus, and resorptive function at 13 weeks, while Morison (1934) stated that urine containing all the standard normal constituents has been found in a fœtus with only three layers of functioning glomeruli. Otherwise fully developed infants, however, have from time to time been born either devoid of kidneys or else without patent urinary passages (Englisch, 1881; Preyer, 1885). So the placenta is competent, if need be, to deal with *all* fœtal fluid excretion, and we can regard the development of the renal circulation and the associated intra-uterine renal performance as graduated exercises which prepare the organ for its post-natal functioning.

At birth the kidney volume is 6·5 ml., and thereafter it rises to reach its final value of 120 ml. at the age of about 16 years (McManus, 1950; *see*, however, Parade, 1926). There is increase in size[2], but not in the total number, of the glomeruli, and, contrary to what obtains in some lower animals, the diameters of the basal and cortical units tend to approximate in course of time; Peter *et al.* (1927) said they were equal at three and a half years. The glomeruli become more spaced out, partly because the cortex increases in size relative to the medulla, partly because the tubular portion enlarges more than the glomerular. Most of the basal glomeruli have flat epithelial covering at four months, but traces of high epithelium persist on cortical glomeruli up to between the fourth and fifth year (Peter *et al.*, 1927). The marked indications of lobulation visible on the surface of the fœtal kidney are smoothed out in post-natal life.

On the functional side, the story is incomplete and its parts inadequately interrelated. It is generally agreed that for the first month or so (*see* e.g. Lasch, 1923; West *et al.*, 1948) the infant's kidney is working relatively imperfectly or immaturely, and with no great reserve against additional stresses. On the basis of surface area, however, the mannitol clearance is normal after the first month, and the adult value for effective renal plasma flow may be reached as early as 30 weeks (West *et al.*, 1948), while urea clearances of children of 2 years and over are the same as those of adults (McIntosh *et al.*, 1928), and children between 4 and 14 years of age gave adult responses to concentration–dilution tests of the Volhard type (Holten, 1931). Figures for blood pressure are very differently given by various authors, e.g. Woodbury, Robinow and Hamilton's (1938) finding of 80/46 mm.Hg in the umbilical artery of a prematurely born 9 months' baby is appreciably higher than many values given for the level at ordinary birth. In general, however, there is agreement about a gradual rise from birth to puberty or somewhat later.

We cannot, from the foregoing evidence, produce any very precise and connected account of the post-natal maturation of the human renal vascular system and circulation, and the only statement (Nash, 1950) suggesting a nervous control of that circulation in its early stages needs some amplification and testing before it can be accepted as evidence. We can, however, believe that at latest by puberty or thereabouts the kidney and its circulatory arrangements are fully developed, in which case we need, to complete this section, knowledge about the length of time during which, in the healthy subject, the state of 100% renal efficiency can continue. The answer is an entirely satisfactory one, namely that it can last, if need be, for so long as a century! For McManus (1950) describes a kidney from a male negro who died in his hundred and fifteenth year, and the organ in question showed nothing abnormal apart from a very few hyaline thickened portions in the glomerular basement membrane. This finding about the kidney as a whole presupposes an adequate renal circulation during the same length of time, and should encourage the clinician in his efforts to prevent departures of that circulation from the normal or, where that is not possible, in his efforts to nullify pathological influences before they have produced irreversible changes.

Anatomy [*Abridged*]

Arteriovenous connexions by-passing glomeruli are of importance in connexion with the

[1]Except for these venous end-organs, the fœtal findings are repeated in the adult.

[2]McManus' figures, lower than those of Külz, are 85 μ for neonatal, and 180 μ to 190 μ, with 200 μ as an outer limit, for adult glomeruli.

interpretation of indirect assessments of renal blood flow and with ideas about the routes taken by the blood in its passage through the kidney. Claims made on behalf of some of the connexions previously listed (Franklin, 1949) need close scrutiny on the quantitative side, while a recent addition to the list (Barrie *et al.*, 1950) is as yet unsupported by adequate published evidence; finally, the experimental findings of Simkin *et al.* (1948) still need the complementary demonstration of the vascular channels involved[1].

The renal lymphatics and renal tissue spaces have been little studied in connexion with the renal circulation in its wider sense. McManus (1950), who makes some mention of them, thinks also that the pyramids and the juxtacortical portion of the medulla must receive extra blood through some non-glomerular channels, but provides no direct evidence.

Measurement of the Renal Blood Flow

Direct determinations of the renal blood flow in animals (e.g. by the use of Rein's Thermostromuhr) have not been beyond criticism, and the methods used are not applicable to man. Certain renal clearance tests, combined with determinations of extraction values, have been introduced with the object of resolving these difficulties. The substances used are excreted, it is supposed, entirely from capillary networks (glomerular and peritubular) and are not reabsorbed; further, extraction is maximal in one passage through the kidney, provided the plasma level is not too high. The extraction value, given as a percentage, is calculated from comparison of arterial and renal venous blood samples (the latter collected in man by means of renal vein catheterization), and is below 100 because, it is believed, a proportion of the total renal blood flow passes through non-capillary channels to reach the renal vein.

The substance first used for such purposes was diodrast (Smith, Goldring and Chasis, 1938), and its use led to the figure of *c.* 1,300 ml. p.m. being given for the renal blood flow in adult man. Subsequently, it was found that sodium para-amino-hippurate (P.A.H.) was treated by the kidney in similar fashion to diodrast, but could be more easily and accurately measured, and had other advantages (Finkelstein, Aliminosa and Smith, 1941; Smith, Finkelstein and Aliminosa, 1945). So it supplanted diodrast. Warren, Brannon and Merrill (1944) were the first to determine its extraction in conjunction with renal vein catheterization in normal unanæsthetized human subjects, and in most of these they found values of 88%[2]. The extraction value in the dog is much the same as in man, but in the *decerebrate* cat it is somewhat lower, namely 75 $\pm$ 3% (Oleesky, 1950, following up the initial work of Black and Saunders, 1949).

If the extraction value does not vary during changes in the total renal blood flow, that is interpreted as meaning that the same *proportion* of the total flow continues to pass through capillary channels. Such constancy was found by Van Slyke (1948) in the dog under various experimental conditions, provided the total flow did not drop to below 3% of its initial value. A drop in the extraction value could theoretically be due to a greater proportion of the total renal flow going through non-capillary by-passes, or to pathological changes occurring in the glomeruli or tubules. The extraction value is found to be low after non-lethal total renal ischæmia of some duration, and the time taken for its complete restoration to normal varies with the length of that ischæmia. The length of time during which animals can stand total renal ischæmia without subsequent death rises from rat (Koletsky and Gustafson, 1947) to rabbit (Scarff and Keele, 1943; Badenoch and Darmady, 1947), and from rabbit to dog (Phillips and Hamilton, 1948). So it is, perhaps, even higher in man.

Other features of intrarenal vascular and circulatory activity, apart from the total blood flow, have been investigated by parallel indirect methods and, even if the findings are not always easy to interpret with certainty, the work as a whole has greatly advanced research upon the activities of the mammalian kidney. Unfortunately, there is not space here for any detailed account of the methods and findings and the deductions made from them—reference must be made to the individual papers.

Nervously- and Hormonally-produced Changes in the Renal Circulation

According to Homer Smith (1943, 56–7), under truly basal conditions no tonic vasomotor impulses pass to the kidney, and the renal blood flow is regulated entirely by the autonomous activity of the renal arterioles. If this view is correct, locally intermediated changes in the

[1]According to Dr. P. M. Daniel (1947; and discussion after this Address), degeneration of basal glomeruli can begin in man as early as the teens, and the direct channels resulting from the process might allow passage of 80 μ spheres. Basal glomeruli constituted about 3% of the total in the kidneys investigated by Xuereb (1948).

[2]In two cases, those with the lowest plasma P.A.H. levels, the values were 100%. In a third case it was zero!

blood flow through part or the whole of the organ could theoretically result from variations superimposed upon this basal state by the action of renal vasodilator and vasoconstrictor nerves. Apart, however, from certain of Bradford's (1889) findings, which require re-investigation and analysis before they can be accepted as evidence of renal vasodilator innervation, the effects of reflex, central, and peripheral stimulation of the renal nerves have invariably, I think, been in the direction of renal vascular constriction and therefore, *ceteris paribus*, of reduction in renal blood flow.

In the mammalian species studied, the renal artery in its extrarenal course can constrict in response to nervous impulses, but I believe that it never does so completely. The evidence upon which my belief is based comes from tracheal occlusion tests, carried out in rabbits after one of the main branches of the artery has been denervated (Franklin, McGee and Ullmann, 1950). Such tests, producing severe asphyxia of the subject, result in maximal nervously-intermediated renal ischæmia and in the cases mentioned, as there was no denervation of the main renal artery, this vessel must have given its maximal constrictor response. Denervation of a branch of this artery results in the portion of the kidney supplied by that branch remaining pervious to blood flow, and under the conditions stated such portion did receive a blood supply, though the still innervated neighbouring portions of cortex, to judge from their marked paling, did not do so. The point is of importance, for some have thought that the nervously-produced constriction of the renal artery, with the consequent distal drop in blood pressure, is sufficient to account for the cortical ischæmia. The experiments mentioned favour the view that the interlobular arteries and their offshoots can constrict completely in response to stimulation which results in only partial constriction of the renal artery.

Nervous effects upon the renal vascular system are not, however, normally as marked as in the tracheal occlusion tests, and we should perhaps consider the theoretically possible results of nervous stimulation upon the intrarenal vessels. These are:

(1) A reduction in all intrarenal calibres leaving *some* blood flow through each glomerulus.

(2) Random intra-cortical shutting down of afferent glomerular vessels.

(3) Progressive occlusion of interlobular arteries and their glomerular branches from the capsular region inwards, the extent of such ischæmia varying with circumstances but being maximal when the supply to the basal glomeruli alone still persists. With only these last representatives of the peripheral vessels still patent, there could be medullary congestion or not according to the degree of reduction of the main renal blood inflow and, in certain conceivable circumstances, of constriction of the renal vein; the site of such congestion would depend on the route or routes used by the remaining renal blood flow in its passage to the renal vein.

(4) Occlusion of all glomeruli and arteriovenous communications, with complete arrest of the renal circulation. In my experience this seems to be beyond the scope of normal nervous influences, though total cessation of flow can be produced by administration of adrenaline in massive dosage.

With regard to (1), (2) and (3) above, I think that (2) is unlikely but that (1) should remain in mind, even though there is no very direct evidence for it, on the grounds that the nervous stimulation so far used has perhaps not included the more delicate degrees, and that urine flow can fall without any marked colour change in the superficial layers of the rabbit's kidney. That (3) occurs under a variety of experimental conditions is beyond dispute, but before giving details may I first briefly consider urine flow in relation to cortical ischæmia? If there is any flow, some glomeruli must be pervious to blood, while anuria can be produced if there is no blood flow to glomeruli, if the effective filtration pressure is too low, or if reabsorption is complete. Increased urine flow can occur as the result of increased blood flow, increased effective filtration pressure, and decreased reabsorption. Urine flow determinations can, therefore, be of help in assessing circulatory changes, though their interpretation may on occasion be difficult. In the Oxford studies of the renal circulation, this and certain other possible aids were not invoked, but they are now being called into service.

Reverting now to the renal blood flow, I wish to state that our demonstration of the possibility of the complete exclusion of cortical glomeruli from the circulation, with more and more layers becoming affected, from the capsule inwards, as the stimulation increases in intensity and/or duration until finally only the basal glomeruli remain pervious, was perhaps *the* novel addition to knowledge made through the researches of the Oxford team from 1945 onwards. For this pattern of effect,[1] with its apparent parallels in renal pathology, was not

[1]Seen first as the result of nerve stimulation, but later obtained also with hormones and other chemical substances.

appreciated before February 1946, when Dr. Trueta gave a résumé of our findings to date to a small group of medical visitors. The renal artery being simultaneously reduced in cross-sectional area, the blood of which the cortex is deprived is, for the most part, re-routed to other parts of the body and does not reach the kidney at all. If, however, the total renal inflow falls by less than the amount which the cortex loses, more blood passes through the routes still remaining open to reach the renal vein, and these routes theoretically include not only the basal glomeruli-vasa recta pathways, but also any other arteriovenous communications, unassociated with glomeruli, that may be available—hence my reference to these in the section on anatomy, So there may be hyperæmia in the cortico-medullary junctional zone and/or elsewhere in the medulla. On the other hand, the medulla can, on occasion, be paler than normal (this is so in the film which I shall project), in which case the drop in total renal blood flow has presumably been greater than the amount of which the cortex has been deprived. In the absence of definite evidence of the function of the residual blood flow on its way to the renal vein, and in view of the small proportion of the total resting flow which it represents, it may be somewhat academic to devote too much attention to it, and I have only devoted this much in order to clarify some of the points in Trueta *et al.* (1947).[1] To conclude this mention of the cortical blood flow diversion, I should add that the intrarenal circuit time may be reduced by as much as 40% during its occurrence ; that the blood in the renal vein may become partially or wholly arterial-red in colour and that more rarely the flow may be pulsatile ; that there may be a retrograde passage of blood from arcuate to interlobular veins and ? tubular capillaries, but not right back to the cortical glomeruli ; finally, that the diversion pattern found first in the rabbit has been noted also in the rat, mouse, cat, dog, and (Scott) monkey, i.e. in all the mammals so far investigated. It is, therefore, possible that nervously-intermediated departures from the normal level of renal blood flow in man, are, on occasion, accompanied by similar exclusion of cortical glomeruli from the circulation ; that, conversely, reported rises in the blood flow may have meant re-inclusion of such glomeruli within the circulation.

The nervous regulation of the renal blood flow is mediated through centres in the central nervous system, diverse afferent pathways to those centres, and sympathetic efferent pathways terminating in the renal nerves. Evidence that spinal centres exist in some animals has been obtained in asphyxia studies (Franklin, McGee and Ullmann, 1950), and centres in the brain are in course of being identified, particularly by E. C. Hoff and his colleagues in the University of Virginia. They found (1949) in cats that excitation of the pressor area (foci on gyrus proreus, gyrus sigmoideus, and orbital and mesial surfaces of the cerebral cortex) resulted in bilateral renal cortical ischæmia, provided the renal nerves were intact. Twelve years earlier Green and Hoff (1937) had reported diminution in volume of the innervated, but increase in volume in the denervated, kidneys of the cat *and the monkey* during pressor responses evoked by electrical stimulation of the cerebral cortex. The more recent work is still proceeding, but I do not think I am justified in adding later information, contained in personal letters, about the results obtained in that and in certain other laboratories.

Afferent pathways to the renal vasomotor centres are numerous. They are present, for instance, in the sciatic nerve, and also in nerves supplying the uterus, intestine, bladder, ureter, and—I suspect—the kidney itself. In the cases of the hollow viscera, an adequate stimulus seems to be sudden distension, especially when combined with indisposition on the part of the smooth muscle to relax. Professor Amoroso has encountered some striking examples in respect of the animal uterus, and I have been told of a human case in which an attempt to induce labour by increasing the uterine distension resulted in acute bilateral cortical necrosis. Direct stimulation of spinal or higher centres by oxygen lack or carbon dioxide excess, or perhaps reflex effects from the kidney via these centres, seem to account for the effects of asphyxia upon the renal circulation (*see* Film Details p. 474).

In our work at Oxford during 1945 to 1947 we noted a tendency for the vessels of the hind-limbs and abdomen to be constricted preferentially in the order femoral artery, abdominal aorta, renal artery, and mesenteric artery—this last might even dilate. This, and further findings led me to the idea of an " order of sacrifice ", which I tested out, in conjunction with Professor Amoroso, by determining the differential reactivity of various arteries to massive doses of adrenaline, injected into the general circulation. Briefly, if such reactivity to adrenaline is

[1]While speaking of this part of our work, may I deal with two other matters? The first is that I personally have never liked the terms "greater circulation" or "lesser circulation" of the kidney, and that I find my overall mental picture of the renal blood flow and its variations the better for their exclusion. The second is that, *in the absence of a precise definition*, I deprecate the use, as much as I appreciate the brevity, of the term "renal shunt" or "Oxford shunt". With a precise, agreed connotation the term would be of great service.

a guide, the skin, limb musculature, renal cortex, gut, brain, and heart, are likely to be sacrificed in that order as the circulation progressively fails. The full story is not ready for publication and I mention these points here partly because they suggest the relative importance of the renal cortical blood flow in the circulatory economy, partly because they explain, I think, the success achieved by Dr. Hingson (1949) in a certain therapeutic use of ephedrine.

The possibility that the afferent and efferent glomerular vessels are not equally affected by adrenaline has often been discussed since the paper by Richards and Plant (1922) appeared, and Homer Smith (1943) interpreted indirect evidence as favouring the view that the efferent vessels are the more sensitive. I have, however, heard at least one alternative explanation and I would not regard the matter as by any means finally settled. Another point in the adrenaline story is unequivocal, namely, that the acutely denervated kidney reacts more rapidly, more intensely, and for a longer time to the hormone than does the innervated kidney (Hartmann *et al.*, 1937 ; Franklin, McGee and Ullmann, unpublished) ; this is very noticeable in the film which I shall project after my lecture.

The other naturally occurring product of particular interest is the antidiuretic hormone of the neurohypophysis. As the result of the work of Verney (*see* Verney 1947, 1948) and of many others, the story of its release in emotional stress and short-lived exercise, through osmotic changes in the blood going to the brain, and in response to injection of acetylcholine or nicotine or to the smoking of cigarettes in unduly trying ways, is well known. What are not yet equally well known are the effect, if any, which it has upon the intrarenal circulation, and the relation of this to the antidiuretic action. The inhibition of water diuresis by emotional stress is independent of the renal innervation, is not caused by endogenous release of adrenaline, is unaccompanied by any appreciable change in the total blood flow through the kidney, and comes on within a relatively short time—some 2 mins.—after the application of the stimulus (Verney, 1948). In appropriate concentrations pituitrin and pitressin can produce paling of the rabbit's and particularly of the rat's kidney surface with little apparent effect upon the calibres of the main renal artery and vein (Trueta *et al.*, 1947), which suggests that any marked action that these hormones may exhibit must be upon structures within the organ. But the experiments which produced these findings need to be extended, and we cannot at present state either fully or precisely what are the renal circulatory actions of posterior pituitary secretion, and of its individual constituents, under physiological conditions. One of the latest discussions of some aspects of the problem is that given by Koella (1949).

Some Questions and Attempts at Answers

The recounting of the effects of nervous and hormonal influences upon the mammalian renal blood flow suggests a variety of questions, such as :

(1) Under what natural conditions may a partial or complete diversion of the renal cortical blood flow occur in man ?

(2) How does it affect kidney functions ?

(3) For how long can it exist without irreversible changes occurring ?

(4) What are these irreversible changes when they do occur ?

(1) Among the natural conditions in which the diversion may perhaps occur are :

(*a*) *Exercise.*—White and Rolf (1948) showed that the " effective " renal plasma flow is reduced and that, in severe exercise, not only may the reduction be as great as 80%, but there may be proteinuria as recovery takes place. This suggests, they stated, though it does not prove, that in strenuous exercise many glomeruli may have their blood supply interrupted, the subsequent proteinuria being due to the reversible temporary damage undergone by these glomeruli during their exclusion from the blood circulation. Rise in plasma glucose, ? an index of increased adrenaline output, was observed when the exercise reached a high level.

(*b*) *Abnormal pregnancy.*—Odell (1947) found reduction in inulin, exogenous creatinine, and urea clearance rates in severe pre-eclampsia, with improvement during the puerperium. " Severe cases ", he added, " cannot be accurately investigated by the usual clearance methods employing collected urine specimens. Consequently, additional evidence is necessary to determine the exact mechanism of oliguria and anuria. The possible etiologic significance of angiospasm is postulated." Very recently Kenney, Lawrence and Miller (1950) have found that in normal pregnancy the afferent glomerular resistance is raised to a minor degree, the glomerular pressure is reduced, and the filtration rate remains normal. In " toxæmia of

late pregnancy ", on the other hand, the renal plasma flow is reduced, the afferent arteriole is constricted, and there are falls in glomerular pressure and filtration rate. In some cases compensation in the way of efferent constriction tends to restore the glomerular pressure to a more nearly normal value. To this evidence, which suggests to the authors *either* a reduction in the blood flow per unit mass, *or* no change in this but a reduction of the total mass, we can add findings such as that of Solymoss (1949), who correlated pre-mortal anuria of an eclamptic patient with cortical pallor and medullary congestion seen in the kidney at autopsy. We have already mentioned acute bilateral cortical necrosis produced by sudden uterine distension. On the whole it looks very possible that diversion of renal cortical blood flow may occur abnormally in human pregnancy, but the case is not, of course, proven.

(*c*) *Severe asphyxia.*—The results found in animals (Franklin, 1948 ; Franklin, McGee and Ullmann, 1949, 1950) suggest that severe anoxia, produced by carbon monoxide poisoning or by a low percentage of oxygen in the inspired air, may reduce the renal cortical blood flow in man, and in this connexion Bradley and Bradley's (1947) paper is not without interest.

(*d*) ? *Acute rapid hæmorrhage*, but not gradual hæmorrhage. This again is a suggestion from results of animal experiments (Trueta *et al.*, 1947 ; Van Slyke, 1948). Van Slyke, using clearance tests in dogs, found that a preferential restoration of the renal blood flow soon followed, unless hæmorrhage had been excessive. He postulated production of V.E.M., as described by Shorr, Zweifach and Chambers, to account for the full recovery, and of V.D.M. to explain the decline, after some measure of recovery, which followed too severe a loss.

Apart from the above conditions, rarer ones such as dioxan poisoning rise to mind. Dioxan has caused acute cortical necrosis in man (Barber, 1934) and tubular necrosis in animals (De Navasquez, 1936), and it can certainly produce renal pallor in rabbits, though the exact mechanism remains to be elucidated (Franklin and Sophian, unpublished).[1]

(2) How the diversion affects kidney function must be considered under two headings, namely, what happens in the still aerobic part of the organ, and what happens in that part which is rendered ischæmic by the diversion. With regard to the former problem, the answer must depend on

(*a*) Whether the reduction in total renal inflow corresponds with the reduction in number of glomeruli, i.e. on whether or not a different proportion of the renal blood flow traverses arteriovenous channels which are unconcerned with the process of urine formation.

(*b*) Changes, if any, in glomerular filtration pressure and other factors.

The functions of the temporarily anoxic portion of the kidney are of interest and, if diversion is at all frequent in normal life, of importance. For such renal tissue is the sole known site of production of V.E.M., which is one of two factors that in large measure control the peripheral circulation, in the body generally, distal to the arterioles (*see* Shorr *et al.*). It increases the frequency and amplitude of the constrictor activity (vasomotion) of the metarterioles and precapillary sphincters, and very greatly enhances their reactivity to the topical application of adrenaline. It is inactivated by the kidney tissue when the latter's oxygen supply is restored. The ischæmic kidney also liberates renin, which acts upon a plasma globulin, hypertensinogen, to produce hypertensin, which raises the blood pressure. The enzyme, hypertensinase, which inactivates hypertensin, is yet another product of the kidney. All together, then, this organ has a multifarious connexion with the regulation of the blood circulation, and there is a considerable interdependence between local and general blood flow arrangements.

The residual blood flow which still passes through the kidney during maximal exclusion of cortical glomeruli may have a maintenance function, including prevention of any serious change in temperature of the organ. But about this there is no evidence, merely ideas about possibilities.

(3) and (4) The third question, "How long can cortical diversion exist without irreversible changes occurring?" is not easy to answer precisely. Hamilton, Phillips, and Hiller

[1]Barium sulphide, used to depilate rabbits, can produce cortical blood flow diversion (Amoroso, Trueta and Franklin, unpublished). More information about the actions of nephrotoxic drugs is being accumulated through the researches of Dr. J. E. Cotes, but I will not anticipate any part of his story, or assess the applicability of his findings to man.

(1948) found in dogs that clamping the left renal artery, after the right kidney had been removed, resulted in death in uræmia if the period of clamping exceeded four hours. Further experiments, by Phillips and Hamilton (1948), showed that renal blood flow was rapidly resumed at a nearly normal rate after twenty minutes to two hours of ischæmia. Clamping the renal artery, however, is a more drastic procedure than producing a diversion of the cortical blood flow, and the only suggestions I have about the length of time during which the latter can be continued without irreversible changes occurring come from some very preliminary experiments carried out by Mr. Sophian and myself. From these it appears that about four hours of continuous diversion, produced by stimulating the renal nerves for thirty seconds every two minutes, may be more than the rabbit's kidney can stand. In one instance, however, there was diminution in extent of a superficial area, visibly affected by the stimulation, during a subsequent recovery period of a few hours' duration. Effects which have been produced by such stimulation have included, according to reports by Professor J. H. Dible and Dr. G. J. Cunningham, localized cortical necrosis, and elsewhere very considerable tissue damage. The results to date are, thus, encouraging but much more obviously remains to be done before any adequate and incontestable story can become available. A point of interest in one experiment was that the unstimulated kidney showed superficial paling during the recovery of the stimulated one.

Summarizing Remarks

From all the information available, it is possible to build up a fair mental picture of the fully developed mammalian renal blood flow and of its variations. In most of the circumstances of everyday life it represents a considerable part of the total cardiac output, and the changes which it exhibits are effected, in so far as the kidney is concerned, through small or moderate adjustments, falling far short of complete occlusion of any vessels, in the degree of vascular constriction. Beyond this routine range of variability more marked falls in intrarenal blood flow can occur in consequence of more serious nervous or chemical action upon the vascular apparatus. There appear to be two main patterns. In the first one, the afferent and/or efferent glomerular vessels are constricted to an extent incompatible with full physiological efficiency of the tubules and (in the case of afferent vascular constriction) of the glomeruli. In the second one, there is actual diversion, in part or in whole, of the blood supply that would normally go to the cortical glomeruli ; with the maximal number of glomerular layers rendered ischæmic, the residual renal blood flow is very small, but it is probably never nil in the absence of general circulatory failure. The more marked changes which I have mentioned probably occur over comparatively short periods as part of the full *physiological* picture, for animals are not always anæsthetized or human beings always under basal conditions, and demands upon the body's reserves of reactivity are, on occasion, maximal. The changes become, on the other hand, part of the *pathological* picture when they continue too markedly for too long a time, and they can result in death when the bounds of recovery possibilities have been overstepped. Short of a fatal outcome, they may leave the kidney functionally less perfect and/or structurally scarred.

Acknowledgments

In the preparation of this paper I have received considerable help from various members of my Staff, particularly Miss E. A. Ullmann and Dr. A. M. Miles ; I have also received several useful suggestions from Mr. G. J. Sophian. To them all I express my thanks.

Film Details

The colour film, photographed by Mr. Douglas Fisher, which was projected after the address consisted of the following parts :

(1) Red stream lines in the renal vein.

(2) Anoxic diversion of the renal cortical blood flow.

Part I (K. J. Franklin, 1948). Part II (E. Ullmann, L. E. McGee, and K. J. Franklin, 1949).

(3) Effects of anoxia and of adrenaline respectively upn the innervated and the denervated kidney.

(4) Excretion of myoglobin by the kidney.

The second item was projected by courtesy of Blackwell Scientific Publications Ltd., the others by courtesy of the Wellcome Foundation Ltd. The subjects used in all four items were anæsthetized rabbits.

POSTSCRIPT

After the lecture and film-projection, Professor T. N. A. Jeffcoate told me of an obstetric case in his recent experience, and very kindly gave me permission to give some account of it here. The patient had concealed accidental hæmorrhage, and anuria from the time of its onset. After twenty-eight hours, when she had recovered from the initial shock, looked well, and had a blood pressure within normal limits, she was operated on and one kidney was exposed. Superficially it did not look pale, but congested. The pedicle was completely denervated without any change becoming apparent on the kidney surface and, when incised, the capsule did not bleed at all, nor did the cortex. On the other hand, so soon as the medulla was reached there was bleeding. The patient died on the tenth day after delivery, and at autopsy both kidneys showed the classical picture of complete cortical necrosis.

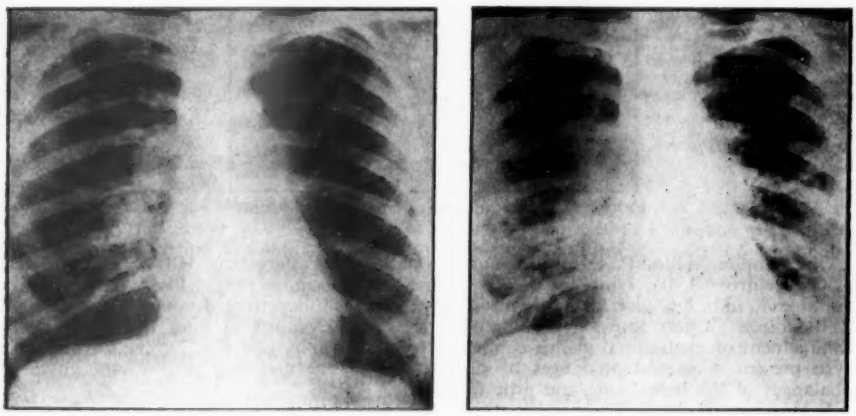
Clinical Section

President—W. A. BOURNE, M.D.

[*January* 13, 1950]



Two Cases of Sarcoidosis of the Lungs with Erythema Nodosum.—O. GARROD, M.D.

I. Mrs. R. S., aged 29, housewife (ex-hospital nurse). (Shown by permission of NEVILLE OSWALD, F.R.C.P.)

Diagnoses.—(*a*) Sarcoidosis of lungs and lacrimal glands. (*b*) Migraine. (*c*) Erythema nodosum.

History.—Quite well until nine months ago when she had an attack of left hemianopia followed within half an hour by numbness of left hand and face for a quarter of an hour, then by severe frontal headache lasting for half an hour. She felt dizzy for several days afterwards. During the following month she had three similar attacks, then a fourth attack in which the hemianopia was to the right.

Six months ago: Typical erythema nodosum of legs and later of arms lasting about a month and accompanied by fever and pain in the knees, elbows and wrists. Since then, she has felt tired and run down.

A.—At time of erythema nodosum. B.—Six months later.

FIG. 1.—Case I.

Five weeks ago: Developed a slight cough and sputum.

One week ago: Noticed slight puffiness of upper eyelids. Has not lost weight.

Annual chest X-rays and Mantoux tests were done from 1939 to 1941 by the Prophit Survey:

Four chest X-rays all negative.

Mantoux tests (1 : 10,000 O.T.)—June 1938: +++ reaction 20 mm. in diameter. April 1939: + reaction, 5 mm. in diameter. August 1940: ++ reaction, 10 mm. in diameter.

On examination (December 1949).—Healthy-looking patient with slight prominence of lateral half of both upper eyelids beneath which the lacrimal glands are distinctly palpable. No other physical signs.

Whilst in hospital she had an occasional evening pyrexia of 99°.

Investigations.—E.S.R. 14 mm. Blood count: R.B.C. 3,900,000; Hb 86%; W.B.C. 6,000 (normal differential). Serum proteins: total 8 grammes % (alb. 5, glob. 3). Sputa Ziehl-Neelsen negative. Radiographs: Skull, hands and feet normal. Chest: In April 1949 (at time of erythema nodosum, Fig. 1A) bilateral hilar gland enlargement. Later films show diffuse mottling compatible with pulmonary sarcoidosis (Fig. 1B). Mantoux test negative to 1 : 100. Lumbar puncture: Pressure and Queckenstedt normal; protein 75 mg.%; globulin faint +; cells less than 2. W.R. and Lange negative. E.E.G.: No significant abnormality noted.

Ophthalmic examination reveals some myopia but no other sign of intra-ocular disease.

II. Miss E. K., aged 51; State-registered nurse. (Shown by permission of A. W. SPENCE, M.D.)

Diagnoses.—(*a*) Sarcoidosis of lungs and phalanges. (*b*) Erythema nodosum.

History (August 1949).—Quite well until five months ago when she noticed a large, raised, tender, bluish-red swelling in the right thigh which lasted for about three months. Since then, numerous similar lesions, from half an inch to three inches in diameter, have appeared on both legs and thighs. For a few months she has noticed increasing breathlessness.

On examination (August 1949).—About seven typical lesions of erythema nodosum were present on the flexor and extensor surfaces of the legs and on the thighs. There were also a few small infiltrated plaques resembling sarcoid lesions on the backs of the legs and on the thighs.

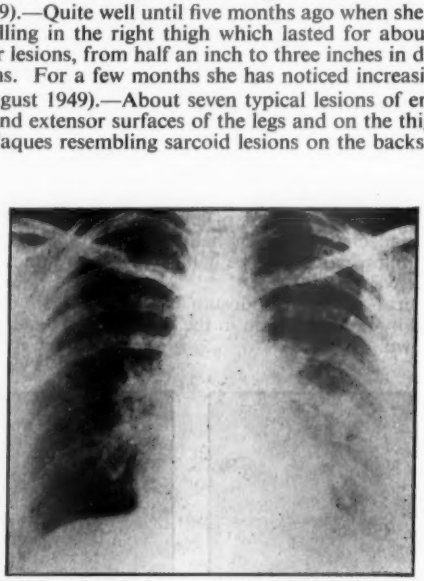


FIG. 2.—Case II at time of erythema nodosum.

Investigations.—Blood: E.S.R. 25 mm. in one hour (Westergren). Hb 102%; W.B.C. 5,500 (neutros. 3,905, lymphos. 1,320, monos. 110, eosinos. 165). Plasma proteins 7 grammes% (alb. 5·6, glob. 1·4). Mantoux test: 1 : 1,000 negative; 1 : 100 weak positive. Radiographs: Chest shows typical appearances of sarcoidosis in both lung fields and enlargement of mediastinal glands confirmed by tomography (*see* Fig. 2). Hands: Small cysts present in second phalanges of right index, middle and ring fingers, and in first phalanges of left index, ring and little fingers.

Subsequent progress.—The erythema nodosum subsided two months after she attended hospital. She has remained well apart from some breathlessness. No treatment has been given.

Chronic Lymphatic Leukæmia with Hæmolytic Anæmia. Splenectomy.—M. S. R. HUTT, M.D., M.R.C.P. (for J. S. RICHARDSON, M.V.O., M.D.).

Mrs. A. P., aged 60, first attended hospital in April 1948 with a bad attack of pharyngitis. Routine examination revealed slight enlargement of the spleen.

Blood count.—R.B.C. 4,500,000; Hb 80%; W.B.C. 22,300 (polys. 55, lymphos. 43, monos. 1, eosinos. 1%).

Diagnosis.—Early case of lymphatic leukæmia. Patient was kept under observation

March 1949: Dragging pain in the abdomen, weakness and tiredness. Examination now revealed marked splenomegaly and enlarged glands in the left axilla. She appeared to be slightly icteric.

First admission.—29.3.49: R.B.C. 3,600,000; Hb 66%; W.B.C. 53,000 (polys. 16, lymphos. 77, monos. 4, eosinos. 1, basos. 1, transitional myelos. 1%).

13.4.49: R.B.C. 2,300,000; Hb 45%; W.B.C. 29,000 (polys. 11, lymphos. 89%).

Sternal marrow showed 73% of lymphocytes, confirming the diagnosis of lymphatic leukæmia.

15.4.49: Blood transfusion (3 pints).

20.4.49: Radiotherapy started.

28.4.49: Patient definitely icteric. Icteric index: 16. Urine contains excess of urobilinogen. Race-Coombs test positive. Blood transfusion (3 pints).

29.4.49: R.B.C. 3,000,000; Hb 66%; W.B.C. 13,200 (polys. 23%, lymphos. 72%). Radiotherapy stopped in view of fall in white count. Discharged. Clinically slight improvement. Anicteric.
13.6.49: Hb 90%.
4.7.49: Seen in follow-up clinic complaining of increasing dyspnœa and tiredness. Clinically anæmic and icteric. Readmitted. Hb 53%.
6.7.49: Transfusion (cells from 4 bottles).
9.7.49: Hb 62%.
10.7.49: Icterus deeper. Urine contains excess urobilinogen.
13.7.49: Hb 48%; W.B.C. 53,700 (polys. 22%).
15.7.49: Transfusion (cells from 4 bottles).
18.7.49: Hb 49%; retics. 12%; fæcal urobilinogen 2,900 mg.
21.7.49: Transfusion (cells from 8 bottles).
24.7.49: Hb 88%.
27.7.49: Splenectomy carried out.
4.8.49: R.B.C. 4,500,000; Hb 78%; W.B.C. 30,000 (polys. 24%, lymphos. 71%).
24.8.49: R.B.C. 4,500,000; Hb 82%; W.B.C. 29,000 (polys. 9%, lymphos. 87%). Discharged, symptom free.
24.10.49: Seen in follow-up clinic. Feels very fit. Blood count: R.B.C. 5,000,000; Hb 108%; W.B.C. 26,000 (polys. 21%, lymphos. 75%).
21.11.49: R.B.C. 5,100,000; Hb 102%; W.B.C. 20,000 (polys. 35%, lymphos. 58%).

Erythromelalgia in One Lower Limb.—GERALD SLOT, M.D.

V. S., female, single, aged 46, complained of pain of the lumbago kind, in the back of her leg.

Prolapsed disc was diagnosed and she was operated on in June 1948 by Mr. E. H. T. Hambly when an inflamed fifth lumbar spinal nerve root on the left side was found.

Investigations by Mr. J. B. Kinmonth at St. Bartholomew's Hospital: Angiograms showed there was no organic obliteration in either the arteries or veins and the symptoms of the foot were of the spastic type.

The pain continued and the question of a lumbar ganglionectomy was considered. Dr. J. Aldren Turner found no evidence of a root lesion and considered that some psychiatric treatment would help. The patient attended a Psychiatric Department once but did not continue. Since then she has been manipulated twice but still complains of pains at the bottom of her back and down the left leg, and blueness of the left foot.

Blood count (1.11.49).—R.B.C. 5,100,000; Hb 100%; C.I. 0·98; W.B.C. 6,000 (neutros. 57, basos. 1, lymphos. 39, monos. 3%).

B.S.R. (Wintrobe) 1st hour 13 mm., 2nd hour 30 mm.

X-rays of back and pelvis negative.

There is some sensory loss over the lower part of the left leg and the left knee-jerk is diminished. Lower limb is blue and colour increases as does pain in dependent position. Pulses of foot are felt.

The diagnosis is between erythromelalgia or ischæmia and suggestions for treatment are invited as her pain has so far resisted all forms of therapy.

POSTSCRIPT.—She has since had a sympathectomy and this has helped considerably.

Dr. A. C. Dornhorst: The outstanding feature of this foot is that the skin flow is much reduced. This can be demonstrated by emptying the veins and then seeing how long they take to refill while gentle constriction is applied proximally. The arterioles must therefore be either occluded or constricted and it is the venules that are dilated and which give the high colour. I do not think the term "Erythromelalgia" should be applied to this condition. If in this case the dorsalis pedis artery were impalpable one would have no hesitation in saying that it is a typical ischæmic foot with "rest pain". However, since the dorsalis pedis pulse is full, the smaller distal vessels must be either occluded or in spasm. As far as I can make out the history is not at all episodic and I think this makes spasm very unlikely. I think it is, therefore, ischæmia due to obstruction of the small distal vessels.

Dr. F. Parkes Weber considered that, whatever the exact ætiology might be, the case could be termed "chronic erythromelalgia of one lower limb". Acute cases might completely subside with or without special treatment. He remembered the complete disappearance of the erythromelalgic symptoms in an acute case. The patient (a woman) was found to have splenomegalic polycythæmia of the Vaquez-Osler type and was under observation till shortly before she left England. There was no recurrence of the erythromelalgia, which had been limited to one lower limb. A rare condition of one-sided red turgid hand in young women appeared to be partly of psychoneurotic origin.

Arteriosclerosis. Thrombosis of Iliac Arteries.—J. B. KINMONTH, M.S., F.R.C.S.

G. H., male, aged 50; a plumber.

History.—Twelve years' intermittent claudication in both calves, gradually becoming worse.

The right leg is worse than the left and has almost continuous rest pain with numbness and coldness in the foot.

State on admission in December 1949.—Erythrocyanosis of right foot which was colder than the left. Moderate postural colour changes in right foot. Pulses absent below the femoral artery on both sides.

Straight X-ray.—Calcification in anterior and posterior tibial arteries of both sides.

FIG. 1.

Aortography (January 3, 1950. General anæsthesia).—This outlined the arterial tree from the abdominal aorta downwards into the thighs and is herewith reproduced (Fig. 1). The chief points of interest are the block in the right external iliac extending as far as the common femoral the faint outline of which, filled by collaterals, is just discernible on close examination. The right internal iliac artery and branches are well filled.

On the left side the external iliac is patent and well filled with dye but the internal iliac is not to be seen and at its expected point of origin from the common iliac there is a well-marked notch presumably due to thrombosis.

Operation (January 7, 1950).—Thoraco-lumbar sympathectomy.

Progress after operation.—Forty-eight hours after operation measurements of the blood flow in the right leg during reactive hyperæmia (Dr. Dornhorst) showed it to be twice the pre-operative rate.

The rest pain in the right leg and foot has been relieved.

Comment.—Angiography showed, as no other method could, the high level of the obstruction and the need for a sympathectomy extending somewhat higher than the routine lumbar one if the collaterals around the blocked segment were to be denervated.

Elephantiasis of Left Lower Limb.—JOHN F. R. BENTLEY, F.R.C.S.

Mr. H. first came under observation in September 1942, when he complained of swelling and aching in the left ankle of gradual onset over the past one and a half years. He gave no history of previous trauma or relevant disease. There was no family history of elephantiasis.

On examination.—The only abnormalities detected were: (1) Pitting œdema of the left ankle; (2) swelling of the left inguinal glands; (3) the presence of a button-like disc 1 cm. in diameter, brownish-purple in colour, with a scaling centre situated on the back of the left calf. This had been first noticed at the age of 10 years.

The skin lesion was excised for histological examination.

Report.—"The 'tumour' shows only a subepithelial immature cellular connective tissue with scanty lymphocytic infiltration. There is no evidence of a specific inflammatory cell exudation or reaction. The surface epithelium is a regular normal cell layer."

FIG. 1.

At a later date the swelling of the ankle spread upwards to involve the rest of the leg and thigh, there being transient exacerbations and remissions. During this period investigations included full blood count, which was essentially normal, and W.R. and Kahn tests which were negative. In the middle of 1943 the enlarged inguinal glands were excised with the hope of removing an inflammatory focus that might be aggravating the condition.

Operation notes.—"Vertical inguinal incision. Flat mass of fibrous tissue almost replaces the inguinal glands and thick trunks of fibrous tissue (? lymphatic channels) pass off down the leg, a few deeply and upwards, and some laterally."

Histological report on specimen.—"Sections from this tissue represent the results of some inflammatory lesion resulting in extensive lymphatic gland fibrosis with sclerotic changes in lymph cords and companion vessels. Only occasional collections of lymphoid cells remain in the glands, the normal architecture being completely destroyed. No sign of germ centres now remain, nor is there evidence of the former gland reticulum. Aerobic and anaerobic cultures do not yield any growth."

Up to the present date the leg has continued to increase in size without beneficial effects from elevation, elastic stockings or massage. Radiographs of the two lower limbs in November 1949 show no difference in the size of the bones or changes in the bony structure. During the past week Frei-Hoffmann test has been negative.

The present condition is seen in Fig 1. The swelling is solid except for the foot where it pits on pressure. It is not distributed evenly, but shows excrescences which do not correspond with any anatomical structures. The toes are not œdematous or enlarged.

The weight of the limb is proving a considerable burden and the question of amputation or a plastic excision of subcutaneous tissue is being considered.

Dr. F. Parkes Weber agreed that the case was one of non-tropical elephantiasis of one lower limb, but he did not think it was of neurofibromatous origin. There was no real evidence of any neurofibromatosis. Even if the small superficial lesion which had been excised from the back of the leg was a molluscous fibroma, its presence was no proof that the patient had neurofibromatosis. It had existed in a stationary condition from early life; probably one in about every two hundred persons had one or two small molluscous fibromata from childhood, without having "neurofibromatosis". He (Dr. Weber) said that he regarded the case as one of chronic progressive lymphatic (? fibrotic) obstruction of the affected extremity, which had to be termed "idiopathic". It perhaps might be suggested that the mass-excision of lymphatic glands from the left groin had accelerated the elephantiasic swelling of the limb.

Malignant Mediastinal Teratoma.—F. V. GARDNER, M.D.

P. A., male aged 30. May 1949: Attended a chest clinic complaining of a single small hæmoptysis. A.P. and lateral teleradiograms normal. 17.8.49: Admitted to the Royal Free

Hospital complaining of five weeks' continuous dull substernal pain and dyspnœa on exertion.

On examination.—Irregular fever to 100°; pulse 90–120; expansile pulsation visible over left upper chest; large pericardial effusion with partial left lower lobe collapse. No lymphadenopathy.

Investigations.—Teleradiograms (Figs. 1 and 2) showed large pericardial effusion and a rounded mass lying in the anterior mediastinum and extending outwards into the left upper zone.

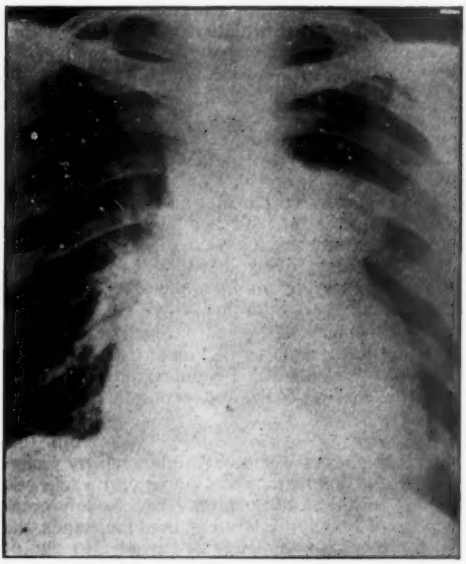

FIG. 1.—Teleradiogram.—A.P. (17.8.49) showing pericardial effusion and rounded mass extending into the left upper zone.

FIG. 2.—Teleradiogram left lateral (17.8.49) showing mass in the upper anterior mediastinum.

Hb 75%; W.B.C. 8,300, normal differential. E.S.R. 27 mm. W.R. negative. Pericardial fluid: straw-coloured, 600 cells/c.mm. 56% polymorphs, 44% lymphocytes; also degenerate cells with large and deeply staining nuclei, suspicious but not diagnostic of malignancy. Bronchoscopy showed nothing abnormal.

Treatment.—Full course of deep X-ray therapy to mediastinum.

Course.—Fever, anæmia and pericardial effusion increased during radiotherapy and congestive cardiac failure developed; no significant decrease in size of tumour mass. Thereafter paracentesis of the pericardium, blood transfusions and general measures improved the local and general condition and the cardiac failure and pericardial effusion disappeared. The mediastinal mass, however, increased in size. Teleradiogram 10.11.49 (Fig. 3) showed no pericardial effusion; the mass seen in the earlier films was larger and below it was an irregular rounded mass extending outwards from the left border of the heart. 16.11.49: Thoracotomy: a large vascular necrotic tumour was found situated in the anterior mediastinum and extending into the left upper lobe. Biopsy report: malignant teratoma. Thereafter the patient's condition deteriorated rapidly and he died on 12.12.49.

Autopsy (Dr. A. G. Stansfeld).—A massive tumour arising in the upper anterior mediastinum extended from the thoracic inlet above to the diaphragm below, enveloped the whole anterior aspect of the heart and reached the lateral chest wall on the left side, causing collapse of the left lung from pressure. Hæmorrhagic metastases in both lobes of the liver. Testes normal. Histology: Malignant teratoma, primary growth and liver metastases showed mixed epithelial and mesenchymal components.

FIG. 3.—Teleradiogram.—A.P. (10.11.49) showing no pericardial effusion; the rounded mass is larger and there is an irregular mass below it continuous with the heart shadow and extending into the left lung field.

Comment.—The extensive pulsation of the upper left chest was an unusual feature and was presumably transmitted pulsation due to the attachment of the tumour to the great vessels. The position of the tumour and the lack of response to radiotherapy made the diagnosis of malignant teratoma most probable in spite of the entirely normal teleradiogram only three months before admission.

Lymphosarcoma of Cheek.—H. A. KIDD, F.R.C.S.Ed.

Girl, aged 12.

At the beginning of November 1949 she developed a swelling inside her left cheek, which was a little painful and interfered with her eating. The doctor treated her with penicillin but the tumour enlarged. She attended the Casualty Department where the lower molar was extracted for caries and ? apical abscess. On 24.12.49 the tumour was aspirated and incised and some thick pus said to have been obtained.

She was referred to the outpatient department and was then seen to have a swelling in the left cheek which was not attached to either upper or lower jaw. She was admitted to hospital that day.

On admission there was some adenitis on the left side of the neck, the glands being small and soft. There was considerable trismus and an X-ray of the antrum showed mucocele in left antrum along lateral wall in particular; the lateral wall showed unerupted wisdom in high position. Swab from ulcer: "Numerous Gram-negative bacilli. Few Gram-negative diplococci and Gram-positive cocci. Cultures (aerobic-anaerobic). Mixed growth of *N. catarrhalis*, diphtheroids and non-hæmolytic streps." Intermittent pyrexia not exceeding 100° at night. The condition was thought to be either actinomycosis or a sarcoma arising primarily from the cheek (Fig. 2).

3.1.50: A large fleshy tumour was exposed and a biopsy performed. Section report: "Acutely inflamed granulation tissue. Condition may be actinomycosis but no positive sign of this was seen. No evidence of malignancy seen."

Treatment with penicillin and streptomycin for twelve days, but the tumour continued to enlarge rapidly.

8.1.50: Biopsy aspiration of tumour which was still enlarging rapidly. Pathological report on film: "*Slides. Thinner film*: numerous R.B.C. and round cells resembling primitive lymphocytes. Almost certainly neoplasm. Malignancy cannot be excluded. *Thicker film*: Mainly R.B.C. with a smaller number of polymorphs, a few lymphocytes and an occasional larger round cell. *Material in saline*: Gram: No organisms seen. Aerobic culture, Anaerobic culture: both sterile."

Diagnosis of lymphosarcoma was made and patient transferred to the Royal Cancer Hospital for radiotherapy.

POSTSCRIPT.—Radiotherapy was given at the Royal Cancer Hospital, the patient receiving the following treatment:

January 17 to 26: H.V.T. 220 Kv max. 945 r, min. 700 r in nine days.

February 14 to March 23: Teleradium 10-gramme unit. Dose to primary max. 4,700 r, min. 2,850 r. Dose to skin 5,700 r in thirty-eight days.

FIG. 1.—18.1.50.

FIG. 3.—18.4.50.

FIG. 2.—25.1.50.

[Photograph taken after treatment has been kindly lent by Professor Smithers.]

There was considerable reduction in the size of the tumour and her general condition is good, as shown by the photograph (Fig. 3) taken on 18.4.50.

June 7, 1950: Examination now shows no evidence of residual tumour, but she has developed a secondary deposit in the innominate bone.

[*February* 10, 1950]

Demonstration of Honeycomb Lungs.—NEVILLE OSWALD, F.R.C.P.

The clinical, radiological and pathological features of a dozen cases are demonstrated in which there are thin-walled cysts distributed uniformly throughout the substance of both lungs. The frequency of spontaneous pneumothorax and of right heart failure is to be noted. The cysts may be part of a general disorder and occasionally occur in any of those three closely related conditions: the Letterer-Siwe disease, Hand-Schüller-Christian disease and eosinophilic granuloma of bone. They may be present in tuberous sclerosis and other similar mesodermal dysplasias, so far having been only recorded in adults. In the majority of instances, however, there is no evidence of disease outside the lungs, such cases falling into two groups. In children and young adults a developmental defect is the most likely cause and spontaneous pneumothoraces, frequently bilateral, are common. In later life infection plays a prominent part, with bronchitis and bronchiolitis leading to bronchiolar

distortion; spontaneous pneumothorax is unusual in such cases but death from right heart failure is likely to occur within a couple of years of the onset of troublesome symptoms.

The radiological features are characteristic but variable. In the developmental type thin-walled cysts are clearly seen; but associated bronchitis, heart failure or the infiltration of a general disorder may render them less distinct in a fully expanded lung. They are always much more easily detected during spontaneous pneumothorax. Iodized oil does not enter the cysts on bronchography.

Case report.—A sailor aged 27 was admitted to hospital with two months' history of cough and sputum. Five days before admission he woke in the morning with substernal pain and breathlessness. There was no significant previous history and radiographs taken as recently as eighteen months before had been passed as normal.

On examination his general condition was good and no physical abnormalities were detected apart from the signs of right spontaneous pneumothorax.

Radiographs and tomograms of his chest showed thin-walled cysts throughout both lungs, being more clearly seen on the side of the pneumothorax. (Figs. 1 and 2.)

FIG. 1.—Honeycomb appearance during spontaneous pneumothorax (tomogram).

FIG. 2.—Honeycomb appearance in expanded lung (tomogram).

His lung subsequently expanded and since then he has not been seen at hospital.

Comment.—The radiological appearances are those of the developmental type of honeycomb lung. It is possible that more spontaneous pneumothoraces may occur and that eventually he will develop right heart failure. The history of bronchitis for a few weeks before the lung collapsed is characteristic and it is possible that his infection threw an extra strain upon his thin subpleural bullæ.

A Rib "Tumour".—G. E. VILVANDRÉ, M.R.C.S., L.R.C.P., F.F.R.

Patient, male, aged about 45, was sent to be radiographed with a suggested diagnosis of a lesion in the left upper zone. The history on further investigation was that four weeks previously he had had some elevation of temperature. He had not felt well for some time, and suffered from repeated colds. There was a pleural rub on the left upper region.

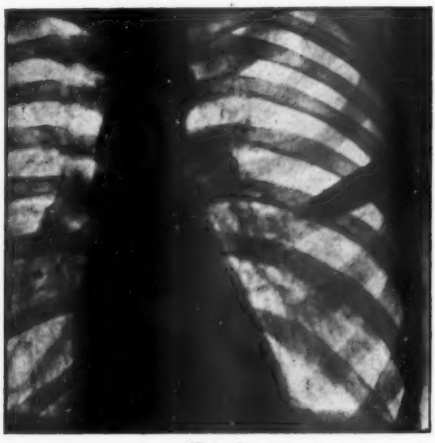

FIG. 1.

A chest radiograph showed a density of the fourth left rib, the lung fields were negative.

On examining the patient some swelling of the soft tissues was palpable. The possibility of a new growth was to be excluded. A Wassermann reaction was found to be negative, and a subsequent radiograph showed no appreciable change. Radiographs of the skull and pelvis showed normal bones and no suggestion of Paget's osteitis deformans.

There is, however, no evidence here of Albers-Schönberg disease and the irregular masses of condensed bone as seen in *melorheostosis* Léri are not present.

The diagnosis of Paget's disease in a single bone (rib), though not common, has been reported.

POSTSCRIPT (June 1950).—The case is being followed up and when last seen two or three months ago there was nothing new.

Wandering Pulmonary Infiltrations with Eosinophilia.—C. P. PETCH, M.D.

Mrs. M. P., aged 50.

History.—Admitted to St. Helier Hospital on four occasions, with wheezing respirations, cough and fever. The first two illnesses were severe, the third less so with only three weeks' fever, the fourth mild, with fever for only one week. In the intervals she has been perfectly fit apart from a feverish cold which was not accompanied by any chest signs or abnormality on investigation. She has never been abroad.

Examination during the acute phases showed rhonchi throughout both lungs, with areas of dullness and crepitations corresponding to the major radiological changes. A transient erythematous rash was attributed to a barbiturate sedative, and disappeared when the drug was withdrawn.

Investigations.—Radiographs of the chest show that opacities have appeared successively in all parts of the lung fields, finally with complete resolution. During what seems to have been her worst period, in 1946, small effusions obliterated the costophrenic angles, first on the right, later, when the right had cleared, on the left. Still later in this illness the cardiac shadow enlarged, but finally returned to normal. Each illness has been accompanied by a high white cell count and marked eosinophilia; figures for the 1946 attack are given:

	Total W.B.C.	% eosinophils	Total eosinophils
11.3.46	17,500	52	9,100
25.3.46	14,200	29	4,110
2.4.46	13,100	24	3,140
8.4.46	13,000	17	2,210
15.4.46	10,400	20	2,080
23.4.46	21,600	50	10,800
30.4.46	18,000	55	9,900
6.5.46	16,700	64	10,600
21.5.46	15,600	61	9,510
27.5.46	15,000	57	8,550
3.6.46	10,200	61	6,720
12.6.46	9,700	29	2,810

Similar counts were recorded in 1947 and 1949.

No evidence of metazoan parasitic infestation has been found. Sputum, urine, stools showed no significant abnormality. E.C.G. physiological.

Treatment has been on symptomatic lines. The administration of arsenic produced a violent reaction and was discontinued.

Comment.—This case differs from the rather similar group described by Löffler in being more severely affected. Tropical eosinophilia differs in its country of origin and response to arsenic. A case very similar to the present, with three relapses, has been recorded from the U.S.A. by Ham and Zimdahl (*Ann. intern. Med.*, 1948, **29**, 488). At present a descriptive title for the condition would appear best. Parasitic infestation (e.g. Ascaris) may produce a similar picture, but cannot account for all cases.

Dr. A. T. M. Roberts: These cases of transient pulmonary infiltration with blood and sputum eosinophilia usually arise in asthmatics, though in some cases the asthma or the eosinophilia may be absent. They do not form a precise clinical entity, but vary infinitely in symptomatology, severity and duration from a mild localized infiltration similar to Löffler's syndrome to a severe condition resembling, and often forming, part of the picture of polyarteritis nodosa. Pulmonary tuberculosis may be suspected and even carcinoma of the bronchus, if the lesion has a segmental distribution.

Pathologically, though atelectasis is suspected by some workers, it is more probable that the fundamental change is a hypersensitive reaction to a known or unknown antigen, occurring in the pulmonary blood vessels. In the mildest form a condition similar to skin urticaria arises, with capillary dilatation and exudation of serum into the surrounding alveoli. In more extensive cases, such as that shown, the reaction around the blood vessels is more severe and granulomata form, followed eventually by pulmonary fibrosis. This fibrosis may lead to scattered areas of characteristic "cyst-like" bronchiectasis. In the most severe cases areas of arterial necrosis occur indistinguishable from polyarteritis nodosa.

Pleural and pericardial effusions, containing eosinophils, are described in association with these infiltrations, and this patient's radiographs suggest that both these conditions may have been present.

Dr. Neville Oswald: I agree with Dr. Roberts that the infiltrations are probably in the nature of a vascular allergy and are comparable with other allergic manifestations such as urticaria and hay fever. Cases of this sort often have a formidable previous and family history. It is not unusual to start with hay fever in childhood, later to have suffered from asthma and then for the asthma to be replaced to some extent by transient infiltrations. After a period of months or years such patients may revert to their asthma.

Free Nipple Transplant in Breast Reduction and Breast Amputation (with Special Reference to Surgical Treatment in Obesity).—PATRICK CLARKSON, M.B., F.R.C.S.

One case, and photographs of others were shown illustrating free nipple transplants in breast reduction and breast amputation. This method is particularly suitable for the reduction of massive hypertrophy of the breasts, as it is a one-stage procedure in which a final result can be obtained by one relatively short operation. In contrast, the pedicle methods of breast reduction (such as the Biesenberger) have to be done in stages if the breasts are very bulky and dependent. Most cases in which the nipples are more than 3 in. to 4 in. below their normal level need a two-stage reduction if pedicle methods are used. The method of free nipple transplant is very suitable for extremely obese patients who want removal of most or all of the breasts.

The free transplant operation comprises an amputation of the nipples together with an area of about 1½ in. in diameter of the areola, and leaving the erector muscles under the nipple.

At a point 7 in. below the suprasternal notch and 4½ in. from the mid-line a circular area of epidermis 1½ in. in diameter is dissected off the dermis on each side. The amputated nipples are then fixed with many fine silk sutures over these dermal recipient sites. Four sutures transfix graft and dermis at the points of the compass close to the nipple. They are tied over a pad of dry gauze which compresses the nipple. Breast and skin, in excess of that needed to form a small mammary prominence under the nipple, is excised by elliptical incisions placed below the new nipple and including the old nipple site. In cases of extreme obesity

FIG. 1.—Breast amputation with free transplant of nipples. Shows pre-operative condition of breast. This patient's weight was stabilized at 16 st. (100 kilos).

FIG. 2.—Shows condition two weeks after operation for amputation of the breasts with free grafts of nipples which are complete takes.

a virtual amputation of the breast can be done. This method gives satisfactory results for such cases. In 7 patients all 14 nipples have been complete takes. The restoration of breast form obtained by it has not been as good as that obtainable by pedicle methods. There is some return of sensation to touch in these nipples over a period of a year but little other sensory response. The nipple grafts retain their erectile property.

Exfoliative Dermatitis with Low Plasma Protein, Œdema, Fatty Change in the Liver and a Filling Defect in the Stomach.—J. S. PEGUM, M.R.C.P. (for L. FORMAN, M.D.).

T. P., male, aged 67, a technical refrigerator engineer.

History.—In February 1948 developed a rash on arms and legs. By November the rash had become generalized and swelling of the ankles after exertion was noticed.

January 1949: Admitted to Joyce Green Hospital. The plasma proteins were low and in spite of bed-rest and a high protein diet became progressively lower and œdema increased.

May 1949: Transferred to Guy's Hospital. Generalized exfoliative dermatitis and genera-

lized œdema. Treated with choline and methionine by mouth and plasma transfusions with no improvement.

August 1949: Œdema relieved by mechanical drainage. Following this the skin improved and the œdema returned in lesser degree.

October 1949: Small hæmatemesis. Developed tense ascites.

Present condition.—Marked wasting. Skin shows large degree of recovery but there is marked pigmentation; tense ascites.

Investigations.—26.5.49: Liver biopsy—perilobular fatty infiltration.

22.7.49: Estimation of daily loss of protein through skin 19·3 grammes (average).

26.7.49: Plasma proteins total 4·9 grammes% (albumin 1·95, globulin 2·95).

24.11.49: Barium meal showed large filling defect of fundus of stomach.

This is a case of idiopathic exfoliative dermatitis with unusual features.

The generalized œdema developed after the dermatitis had been present for some months. Associated with this was a plasma protein level found to be consistently low during the period of observation. It was thought that loss of protein by skin exfoliation and exudation might account for the lowered plasma proteins. This loss was measured and found to be 19·3 grammes of protein per day.

A liver biopsy showed perilobular fatty infiltration.

The following explanations of this finding have been considered: (1) That the liver change was primary. (2) That the skin and liver changes were due to a common toxic factor. (3) That the liver changes were secondary to the skin condition due to the production by the skin of a toxic substance of the same sort as has been postulated to account for the liver changes in burns. (4) That the oils and ointments applied to the inflamed skin were absorbed, giving rise to a lipæmia with fat deposition in the liver.

A filling defect in the stomach revealed by barium meal together with complete achlorhydria are suggestive of carcinoma of the stomach.

The tense ascites was a relatively late development and may be due either to pressure from a metastasis on the portal vein or to the development of a cirrhosis of the liver.

POSTSCRIPT (June 1950).—The patient died on 1.4.50. At post-mortem the findings were as follows:

Anasarca, massive ascites and large bilateral pleural effusion. Considerable wasting masked by œdema.

Lungs: Œdema and bronchiolitis.

Cardiovascular system: Hypertrophy of left ventricle. Atheroma of coronaries and of aorta.

Liver: Small, but macroscopically normal. Histology showed areas of focal fibrosis.

Stomach normal: no evidence of carcinoma.

Congenital Bilateral Accessory Parotid Gland Hypertrophy. Cervical Sympathetic Overactivity Due to Scar.—G. QVIST, F.R.C.S.

Man, aged 58, with history of increased sweating on the right side of the face for three years, coming on after eating or smoking. In 1940 he noticed an enlarged gland in the right supraclavicular fossa which broke down and discharged for three months. This was treated with ultraviolet light. Slight discharge again in 1943 for short time.

Patient has had bilateral swellings on face as long as he can remember; diabetes diagnosed in 1948.

Family history.—Father had similar swellings on face. Father and brother have diabetes.

On examination.—(1) Bilateral enlargement of accessory parotid glands. The parotid space between jaw and ear feels empty. Confirmed by sialography. (2) Depressed scar in right posterior triangle fixed deeply. (3) On eating or smoking there is marked sweating on right side of face.

It is suggested that this is a case of stimulation of the cervical sympathetic, due to traction on the cervical scar by the muscles of deglutition (Fig. 1).

This is quite separate from the condition of enlarged accessory parotids which seems to be congenital in origin and is probably unassociated with the sweating syndrome (Fig. 2).

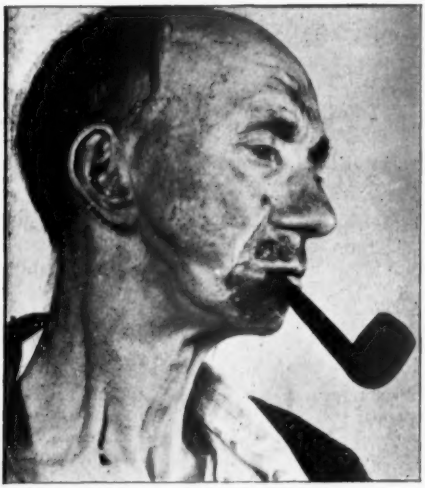

FIG. 1.—Showing scar in neck and sweating of right side of face demonstrated by dye.

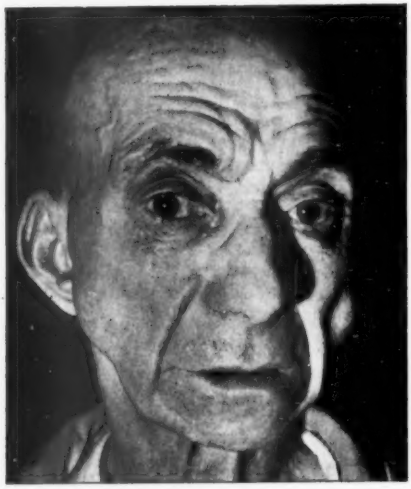

FIG. 2.—Showing bilateral enlarged accessory parotids.

Dr. F. Parkes Weber said he regarded Mr. Qvist's case as an analogue or variant of the auriculo-temporal syndrome (*see* F. P. Weber, *Trans. Clin. Soc. Lond.*, 1898, **31**, 277, and "Rare Diseases and Some Debatable Subjects", 1946, p. 66). In typical cases the scarring is in the parotid region, whereas in Mr. Qvist's case it is just above the sternal end of the clavicle and the sweating associated with eating extends over a large area. The abnormality in the position of the parotid glands is doubtless congenital and has nothing to do with the abnormal sweating.

[*February* 3, 1950]

The Surgery of Otosclerosis

By TERENCE CAWTHORNE, F.R.C.S.

IN December 1946 I gave a Review of the Surgery of Otosclerosis (*Proc. R. Soc. Med.*, **40**, 320) and I should now like to submit some personal impressions and experiences of this fascinating and expanding branch of Aural Surgery.

What I have to say will be based on personal experience in over 400 operations for otosclerosis and some 250 operations on the labyrinth for other non-suppurative conditions.

The operation in general use and which I employ is based on Lempert's nov-ovalis approach, and consists in making a window in the anterior part of the bony external semicircular canal and adjacent ampulla. This opening is covered by a flap derived from the skin covering the anterior wall, roof and posterior wall of the bony external meatus, continuity with the intact tympanic membrane being preserved.

Its proper performance makes considerable demands on the surgeon and calls for practice, patience and self-control. The surgeon must ensure that he is provided with good illumination and adequate magnification, particularly for the most important part of the operation, namely the making of the fenestra. This must be made on top of a mound, so that when the tympano-meatal flap is placed over the fenestra it will invest it closely and seal it off like a rubber patch sealing off a puncture in a pneumatic tyre. Great care must be taken to avoid injury to the membranous labyrinth, or anything that may encourage the formation of excessive fibrous tissue or bone formation over or within the fenestra. Hæmostasis, a fenestra with clean margins, a perilymph space free of blood and of bone debris, an intact membranous canal and ampulla, and a thin intact tympano-meatal flap from which all flakes of bone have been removed, are essential for success. Lempert and his former pupil, Shambaugh, have furthered the progress of the operation by drawing attention to these and other factors. From my own experience I would like to emphasize the value of adequate magnification whilst making the fenestra. A binocular dissecting microscope, which is freely manœuvrable and which has a brightly illuminated field is, I believe, the surest way of achieving a clean fenestra, a clean flap, an undamaged membranous labyrinth and a perilymph space free from bone debris and blood.

Only when this stage of the operation is properly performed can a good and lasting improvement in hearing be expected. The following photographs (Figs. 1, 2 and 3) show the fenestra as it appears at operation under a continuous flow of saline. They are enlargements from the 16 mm. colour cinefilm taken by Mr. E. Gwynne Evans and Mr. Edward Mackie which will be shown at the end of the paper.

Therefore, the closest attention and much practice have to be devoted to the making of the fenestra, and the wise surgeon will ensure that he is not tired out by the preceding steps of the operation, cramped for space by inadequate exposure, handicapped by poor illumination, nor, finally, embarrassed by lack of experience in working in a magnified field.

Other aspects of the operation have been fully dealt with elsewhere, and, provided that the exposure is adequate, both at the time of operation and for the post-operative inspection and treatment of the cavity, and that important neighbouring structures are not imperilled, the details of the soft tissue and bony approach can be left to the individual surgeon. My own preference is for the endaural approach, though, as I have seen when visiting Mr. Simson Hall in Edinburgh, the post-aural approach gives an excellent view. I have still, however, to be convinced of the value of the antauricular approach advocated by Popper.

The bony cortex of the mastoid can be reduced to bone dust by a dental drill or removed by sharp gouges. The drill has the advantage of being more bloodless and, in practised hands, can be very accurate and safe. On the other hand, the reduction of the mastoid cortex to fine bone dust by a drill is a messy, laborious and time-consuming procedure. Having tried

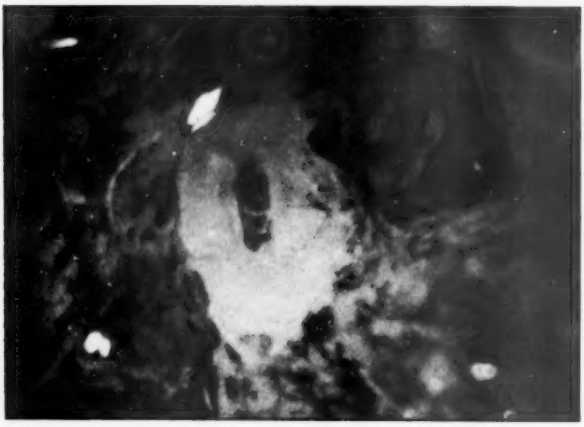

FIG. 1.—Magnified view (× 6) of a newly created fenestra. The top of the fenestra has been cut off and turned over, where it can be seen to the left of the fenestra. The membranous canal with some shreds of endosteal debris and bone will have to be cleared away.

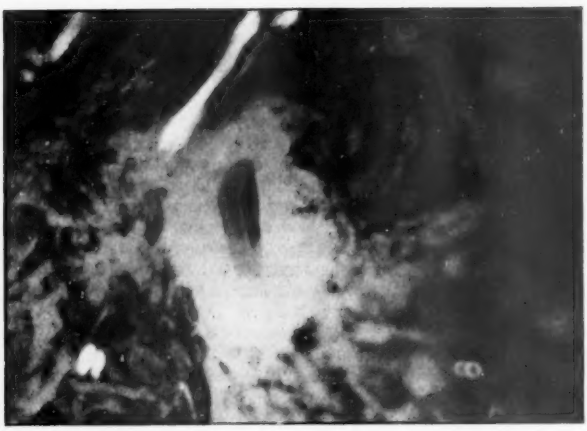

FIG. 2.—The same fenestra as in Fig. 1, after all the shreds of bone have been cleared away.

FIG. 3.—The completed fenestra. The membranous labyrinth can be clearly seen and in the upper part of the fenestra the membranous canal can be seen bending into the ampulla (× 10).

both, I prefer a little blood at this stage to a lot of bone dust, though of course both can be, and are, satisfactorily removed by flushing the cavity with warm saline. In this connexion I should like to emphasize the value of irrigation of the operative field with saline at 100° F. In the earlier stages intermittent irrigation is sufficient, but for making the fenestra continuous irrigation as suggested by Shambaugh is most helpful. It is, however, of some importance to ensure that the irrigating fluid is constantly at 100° F.; for the exposure of the unprotected vestibular labyrinth to gross thermal changes is obviously undesirable, and may augment the post-operative vestibular disturbance.

After removing the head of the malleus, I always cut the tendon of the tensor tympani where it is inserted into the neck of the malleus. By doing this I believe the chance of troublesome clicking or vertigo on contraction of the tensor tympani after the operation is reduced.

Sufficient bone must be removed to allow full freedom of movement under magnification in the region of the fenestra. Aubry, van Eyck, Dohlman, Popper and, lately, Shambaugh advocate a very limited removal of bone and they try to avoid opening the mastoid or even the antrum. I have not, as yet, any experience of this limited approach, though if it will hasten post-operative healing without increasing the risk of undesirable complications from infection it will be an advantage. Skin grafting the raw areas of the bony cavity at the time of operation helps to shorten the healing time.

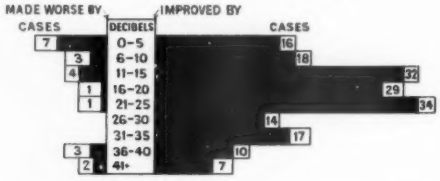
For the first few post-operative days, the tympano-meatal flap and cavity need to be subjected to continuous, gentle and non-adherent pressure. This can be achieved by lining the cavity with strips of oiled silk—Lister's Green Protective—and then packing it with small pieces of marine sponge. Shambaugh, from whom I got the idea of using sponge, employs two relatively large pieces soaked in sulphadiazine cream, but I believe that smaller pieces give a more evenly distributed pressure, and I am not as yet convinced that any local antiseptic is of value.

With regard to the post-operative period, some vestibular disturbance is the rule, due not so much to infection, as has been suggested by some observers, but to the altered physical conditions within the labyrinth. This can best be overcome by the head and balancing exercises developed by Cooksey and myself for the management of the disturbance of balance following vestibular injuries. Campbell has recently reported on the value of dramamine in combating the post-operative vestibular disturbance. Most patients are out of bed on the fourth post-operative day, and leave hospital within the fortnight.

Some degree of post-operative infection of the cavity is common, and though continued discharge may be a nuisance it rarely affects the hearing result, and seems to be due to infection of soft tissue rather than bone.

The results are largely governed by the care with which cases are selected and the skill with which the operation is carried out.

Before, however, considering the selection of cases, I should like to deal with operative results.



Results.—Now when we come to the recording of results, I must confess that I am somewhat at a loss to know how best this should be done. In fact, I would go farther than this and say that no one person, least of all the reporter himself, is in a position as yet in which he can say what is the fairest—or should I say wisest—way of doing this. It is mainly by watching his results that the surgeon can measure his progress and be stimulated to seek for further improvement. Furthermore, by reference to his own results he can offer the most likely and, therefore, the fairest estimate of the amount of improvement in hearing that fenestration in his hands will offer.

Many standards have been suggested for reporting results and the American Otological Society has a sub-committee to enquire into standards for reporting fenestration results, which has already made provisional suggestions. It would, I think, be a great help to all who are interested in this work, if a committee could be set up in this country as well to advise on the best way of recording the results of the fenestration operation, and I would venture to suggest that this Section would be a very appropriate body to undertake such a task.

With regard to my own results, I would prefer to give the figures in terms of decibel improvement or loss for pure tones within the critical range of speech frequencies (512, 1,024 and 2,048 c.p.s.). I have grouped the cases in 5-decibel steps and have included only those patients who have been followed up for eighteen months or more after operation, and I have chosen this time because so far I have not had any patient whose hearing deteriorated after eighteen months. I think that the ideal way of testing the hearing capacity after operation is by means of recorded speech, and Silverman and Walsh have already published some interesting observations along these lines.

The results now to be considered are those from cases on whom I operated by the technique described, between July 1946 and August 1948. Only those of whom I have no record for at least eighteen months after the operation have been omitted.

TABLE I.—HEARING FOR PURE TONES WITHIN THE CRITICAL RANGE OF SPEECH FREQUENCIES (512, 1,024 AND 2,048 C.P.S.) EIGHTEEN MONTHS OR MORE AFTER FENESTRATION FOR OTOSCLEROSIS IN 198 CASES (INCLUDING 5 REVISIONS).

The selection of suitable condidates for surgery from among those deafened patients who hopefully present themselves is no easy task, nor is it a matter about which hard-and-fast rules can be laid down.

The series under consideration does not include any patient who:

(1) Was not thought to be suffering from otosclerosis.

(2) Did not have an intact and healthy tympanic membrane.

(3) Could not tolerate and understand speech with the help of a high quality amplifier.

Each patient selected for operation has, at the time of the first interview, been put into one of three groups, Suitable, Borderline, and Unsuitable, and the distribution in this series has been as follows:

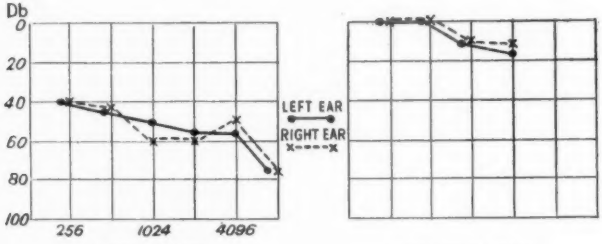
TABLE II

Suitable	..	..	..	107
Borderline	..	..	..	80
Unsuitable	..	..	..	11

In classifying a case of otosclerosis in terms of suitability for operation it is necessary to assess the patient as a whole; taking into consideration the history, the appearance of the tympanic membranes, the tone of the voice, tuning fork and pure tone audiometer tests, and the ability to understand amplified speech. In the present state of our knowledge, I hesitate to give precedence to any one of the significant features of the clinical picture of otosclerosis that I have just mentioned in selecting cases for operation. Instead I would prefer to give, in summarized form, a typical case from each of the three groups.

TABLE III.—SUITABLE

Mrs. O. D., aged 48. History of progressive deafness ten years. Not affected by birth of only child. Hears better in noisy surroundings. No history of deafness in family.



On examination.—Upper respiratory tract healthy. Soft voice of normal timbre.

Tympanic membranes: Intact, normal lustre, mobile on auto-inflation.

Speech (at conversational level): Unamplified, 3 inches; amplified, 12 feet.

Tuning forks (512, 1,024 and 2,048 d.v.): All negative Rinne and normal bone conduction.

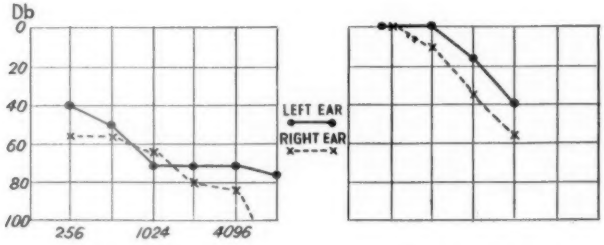
Pure tone audiometer: Maico D.9.

Air conduction. Bone conduction.

Conclusions: Otosclerosis with unimpaired cochlear function. Suitable for fenestration. 50% chance hearing speech at 10 feet. (Operation resulted in hearing speech at 20 feet.)

TABLE IV.—BORDERLINE

Mrs. E. D., aged 45. History of slowly progressive deafness 31 years. Not affected by birth of only child. Hears better in noisy surroundings. History of deafness on mother's side of family.



On examination.—Upper respiratory tract healthy. Soft voice of normal timbre.

Tympanic membranes: Intact, normal lustre, mobile on auto-inflation.

Speech (at conversational level): Unamplified, not heard; amplified, 6 feet.

Tuning forks (512, 1,024 and 2,048 d.v.): Negative Rinne 512 and 1,024. Not heard left, and heard by bone only right, 2,048. Reduced bone conduction 1,024 and 2,048.

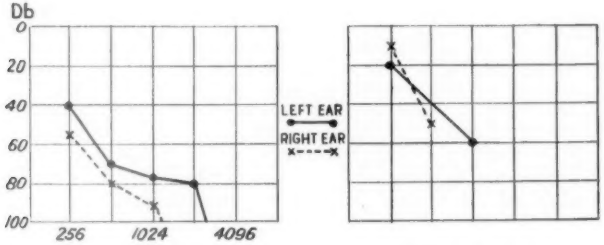
Pure tone audiometer: Maico D.9.

Air conduction. Bone conduction.

Conclusions: Otosclerosis with slight impairment of cochlear function. Borderline for fenestration. 30% chance hearing speech at 3 feet. (Operation resulted in hearing speech at 8 feet.)

TABLE V.—UNSUITABLE

Mr. F. C. H., aged 43. Progressive deafness sixteen years. Hears better in noisy surroundings. Brother also deaf.



On examination.—Upper respiratory tract healthy. Slight alteration in timbre of voice.

Tympanic membranes: Intact, normal lustre, mobile on auto-inflation.

Speech (at conversational level): Unamplified, not heard; amplified, 4 feet.

Tuning forks (512, 1,024 and 2,048 d.v.): Negative Rinne 512 and 1,024 right. Air equals bone 512 and 1,024 left. Positive Rinne 2,048 left, not heard right. Reduced bone conduction 512, 1,024 left and right, and 2,048 left.

Pure tone audiometer: Maico D.9.

Air conduction. Bone conduction.

Conclusions: Otosclerosis with considerable impairment of cochlear function. Unsuitable for fenestration. 20% chance hearing conversation at 1 foot. (Operation resulted in hearing remaining unchanged.)

The following tables show the results in each of the three groups:

TABLE VI.—HEARING FOR PURE TONES WITHIN THE CRITICAL RANGE OF SPEECH FREQUENCIES (512, 1,024 AND 2,048 C.P.S.) EIGHTEEN MONTHS OR MORE AFTER FENESTRATION FOR OTOSCLEROSIS IN 107 CASES CLASSIFIED AS SUITABLE.

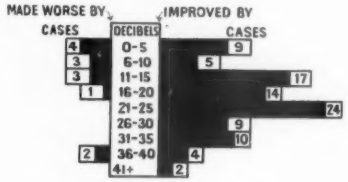


TABLE VII.—HEARING FOR PURE TONES WITHIN THE CRITICAL RANGE OF SPEECH FREQUENCIES (512, 1,024 AND 2,048 C.P.S.) EIGHTEEN MONTHS OR MORE AFTER FENESTRATION FOR OTOSCLEROSIS IN 80 CASES CLASSIFIED AS BORDERLINE.

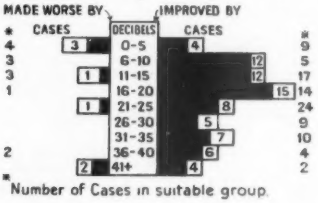

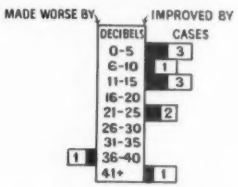

TABLE VIII.—HEARING FOR PURE TONES WITHIN THE CRITICAL RANGE OF SPEECH FREQUENCIES (512, 1,024 AND 2,048 C.P.S.) EIGHTEEN MONTHS OR MORE AFTER FENESTRATION FOR OTOSCLEROSIS IN 11 CASES CLASSIFIED AS UNSUITABLE.

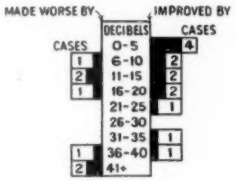
It will be seen from the foregoing tables that the classification of cases is an uncertain business. Some classified as unsuitable do well, whilst others thought to be suitable do badly. In estimating to the patient at the time of the first consultation the chances of success, I have in the past offered suitable cases a 50% chance, borderline a 30% chance, and some unsuitable cases a 20% chance of long-term improvement in hearing. The extent to which the hearing is likely to be improved by operation is of course governed by the original hearing loss. I estimate this on the basis of a possible improvement of 25 decibels for the critical speech frequencies and translate this into terms of everyday hearing.

Indications.—Now I believe that in its present form the fenestration operation is most likely to be successful when the otosclerotic bone is limited to the region of the oval window, and *per contra*, that extensive spread of otosclerotic bone, either over the surface or into the cavities of the bony labyrinth, renders a case unsuitable. Therefore any clinical indication of such extensive growth should be carefully sought for, and, if present, taken into consideration in assessing suitability for operation.



In my previous review of the surgery of otosclerosis I mentioned four signs of poor prognostic significance, and I should now like to add a fifth.

TABLE IX.—SIGNS OF POOR PROGNOSTIC SIGNIFICANCE

(1) Alteration in the *timbre* of the voice.
(2) Intolerance of *amplification*.
(3) Disappearance of *paracusis*.
(4) Reduction of *bone conduction*.
(5) Pink-tinged *tympanic membrane*.

I would suggest that in the first three groups the organ of hearing is definitely at fault. In Group 4, the organ of hearing may be responsible, but I believe that loss of bone conduction can also be caused by widespread otosclerotic bone, particularly if it seals up both labyrinthine windows. In the last group, the tympanic membrane is seen to have a pink tinge due, it is believed, to transmitted colour from the mucosa covering the promontory —the so-called Schwartze sign. This is often associated with other unfavourable signs, particularly loss of bone conduction, and is generally regarded as an unfavourable sign.

TABLE X.—HEARING FOR PURE TONES WITHIN THE CRITICAL RANGE OF SPEECH FREQUENCIES (512, 1,024 AND 2,048 C.P.S.) EIGHTEEN MONTHS OR MORE AFTER FENESTRATION FOR OTOSCLEROSIS IN 20 CASES WITH PINK-TINGED TYMPANIC MEMBRANES.

In the present series, 20 cases were noted as having pink-tinged tympanic membranes, and only 7 of these sustained an improvement of more than 10 decibels for the critical speech frequencies, despite the fact that 12 had been assessed before operation as suitable cases. On the other hand, 7 were made worse. Until I was reviewing the present series of cases I did not fully appreciate the grave prognostic significance of pink-tinged tympanic membranes. I have found that such cases have been the cause of much disappointment, and in future I shall put all such cases in the "borderline" or "unsuitable" category; though by doing so I do want to emphasize that they should not be denied operation provided that they appreciate that the chance of success is slender.

The cause of failure in some instances is only too obviously—and I refer to my own cases—faulty technique, in others faulty selection, and there are some in which the cause of failure is not obvious; but it is only by doing a certain proportion of apparently unsuitable cases that we can advance this work. In 3 out of the 11 apparently unsuitable cases that I operated upon, there was an improvement in hearing of more than 20 decibels for the critical speech frequencies. Therefore although the prospect of improvement is not necessarily bright in cases classified as unsuitable, I do not think that they should be denied operation if there is evidence of effective cochlear function.

Before concluding, I should like to offer a few observations on two other forms of surgical treatment that I have tried.

Removal of stapes.—I have removed the stapes in 23 cases of otosclerosis, all but 4 of which would be classified as "unsuitable". One of the "suitable" cases has retained his improvement for nearly four years. If we can solve the problem of sealing off the oval window and of retaining the tympanic membrane intact and of normal tension, I believe that this might prove to be a most effective and lasting form of treatment, because, after all, it is the natural window; and once the stapes has gone, is unlikely to become sealed over by bone again, as anyone will realize who has seen the oval window under the dissecting microscope.

In another small group, all considered unsuitable, I have performed a fenestration operation and in addition removed the stapes. In all the 4 cases so treated, I believed that the round as well as the oval window was impeded by otosclerotic bone. In none, however, was there any improvement in hearing; but I still hope that in such cases, provided that there is sufficient cochlear function to appreciate and tolerate amplification, some form of operative treatment may be found to be of help, and I intend to continue to search for it.

Sequelæ.—There are two final aspects of this problem that are of considerable physiological interest and which may help us further to appreciate the mechanics of hearing.

I have not, as yet, seen a case of otosclerosis submitted to the fenestration operation in which exposure to loud sounds resulted in a vestibular stimulus. Readers will recall the Tullio phenomenon in which a window made in the lateral canal renders the animal—pigeons, in the cases Tullio described—liable to a vestibular stimulus on exposure to a loud sound.

I had a patient, suffering from Ménière's disease, on whom in 1938 I made an opening into the bony lateral semicircular canal, without disturbing the membranous labyrinth. This patient, after leaving hospital, complained that exposure to any loud sound caused giddiness, and investigation revealed that exposure to a pure tone of 80 d.b. within the range 250–4,000 c.p.s. caused a movement of the eyes and deviation of the head and body. This was relieved by a second operation, in which the membranous external semicircular canal was removed and, as a result, cochlear function destroyed.

Now why is it that Tullio's phenomenon is not seen after the fenestration operation for otosclerosis? For I have not as yet seen it, nor have I knowledge of any record of it. I think that the reason may well be that the Tullio phenomenon is dependent upon unimpeded round and oval windows. I have seen 3 patients suffering from severe and intractable vertigo following a fenestration operation. In each case there was reason to suspect that the foot-plate of the stapes was not impeded by otosclerotic bone. In each case also the hearing had been made worse by the operation and it seemed advisable to consider destroying the remaining but clearly disordered vestibular function. Up to the present I have not seen such a sequel in otosclerosis, though as Shambaugh points out it can occur. I do feel that an artificial opening in the bony vestibular labyrinth is particularly liable to cause troublesome vertigo if the natural openings are unimpeded. For this reason I would hesitate to advise the fenestration operation where there was any reason to suppose that the stapes was mobile.

The other feature that is of particular interest to me is that limited damage to the membranous canal does not, in cases of otosclerosis, necessarily result in a complete loss of hearing. In every case of Ménière's disease in which I have removed all or even part of the membranous semicircular canal, total and irreversible deafness has resulted. I have, however, accidentally torn the membranous external semicircular canal across in 4 of the cases in the present series. In none was the hearing improved; whilst in 3 it was not altered by more than 10 d.b. either way, in the fourth it was made much worse, but was not abolished. In each case the membranous canal was torn across at the posterior end, well away from the ampulla. I hope in due course to report the result of deliberately carrying out a similar procedure in cases of Ménière's disease.

I have some patients whose ear continues to discharge, though this does not necessarily modify a good result; whilst others have a varying degree of narrowing of the meatus.

As yet I have not found it necessary to re-operate on a patient for either of these complications.

In 2 cases there was a facial paresis that cleared up within two weeks. In 31 cases the initial improvement was not maintained, due, I believe, in most instances to a partial or complete closure of the fenestra. On the other hand, 20 cases continued to improve three or more months after the operation, and one only started to improve seventeen months after operation. Finally in one case the hearing in the operated ear was lost entirely. Because of the possibility of making the hearing in the operated ear worse, I make it a rule to operate always on the worse hearing ear first. If this is successful, the other ear can, if desired, be operated on at a later date—not less than a year after the first operation.

With regard to revision operations, I must confess to being disappointed in the results. In the five that I have done in the series under review, I found bone extending into and, as a rule, surrounding the membranous canal. In three of these, the membranous canal was torn in endeavouring to free it from the surrounding bone. In none was there any permanent improvement in hearing as a result of the revision operation. I think that the next time I undertake a revision I shall be prepared if I find the membranous labyrinth entangled in new bone to make a fresh opening in the bony labyrinth, possibly in the posterior canal.

I should like to take this opportunity of saying how much I appreciate the generous help of my friends here and elsewhere for their kindness in entrusting their patients to my care. There is still much more work to be done and many problems to be solved. Above all we should not regard otosclerosis as a purely surgical problem and we should not lose sight of the fact, nor should we let our patients lose sight of the fact, that a good wearable valve-amplified hearing aid rarely fails to improve the hearing in cases of otosclerosis, and that surgery is only part of the management of the patient suffering from this form of deafness.

Finally, I should like to recall the names of those who have made this work possible, and in particular I would mention Jenkins, Holmgren, Sourdille, Lempert and Shambaugh, and to say of them as did Shakespeare in "The Tempest": "Your tale, Sir, would cure deafness."

Mr. E. R. Garnett Passe: *Technique.*—Three major controversies have arisen in the technique of the fenestration operation, namely:

(1) Should we exenterate the mastoid process, or should we be content with as small an approach in the form of an atticotomy as possible, either by the end- or the pre-aural approach? Having used both extensively I am whole-heartedly in favour of the mastoid being exenterated for the following reasons. It is possible to make my long fenestra with a protecting "hood", and to construct and position the flap more carefully, and to facilitate the subsequent dressings with less risk of post-operative infection or excessive granulation tissue formation.

(2) The second question is in the use of the lead burr. Personally I am awaiting the published reports on cases of two years' duration from those using this technique. In the few cases I have used it, sufficient time has not yet elapsed to judge of its value. I feel that the presence of any *noxious foreign body* must *increase* the tendency to excessive fibrous tissue formation from the under-surface of the flap, which, when it occurs, undoubtedly decreases the hearing.

(3) Thirdly, it has been suggested recently by Holmgren that it is not necessary to open the endosteum. Even under a magnification of 10, I find it almost impossible to clean the endosteum of all bone dust and chips without opening into the perilymphatic space. If I can preserve the endosteum I like to turn it down over the lower edge of the fenestration as suggested by Sullivan.

As one of the causes of failure in the restoration of hearing is obstruction of the round window with blood clot, I make a routine practice of thoroughly examining the foramen before proceeding to construct the fenestra. In order to keep the foramen clean during the construction of the fenestra I place in it a small piece of lintene attached to a thread. At the completion of the fenestra the pack is removed.

Healing of the cavity.—It soon became evident to me that the rate of healing was in direct ratio to the dryness of the cavity. Of great help in this respect are frequent dressings and the use of calgitex [1] which I introduced with Blaine in 1948. Skin grafting of the cavity enjoys a certain popularity, but I think that the risk of introducing infection in this way is unjustified. I find my large meatal graft and careful post-operative dressings quite adequate.

The employment of the recruitment test in borderline cases is a great help. I cannot agree with Mr. Cawthorne's observation *re* the inadvisability of operating on cases which show a pinkish tinge of the drum head—surely this may only mean that the membrana tympani is, perhaps, unusually thin.

Results.—Sufficient time has now passed since the fenestration operation was first performed in this country for us to begin to form our own opinion of its value without having to rely entirely upon the results obtained by otologists of other countries. However, there is still a dearth of published records by those of us who are making a specialty of the operation. On reviewing my results which I published last year [2], I find that there has been only slight material change in the percentage of overall improvement. Of my second series performed between three and four years ago the percentage of cases remaining at the practical level is still about 40%. These were all cases of cartilage stopple insertions. During the next three years 611 cases were operated on and from those cases whose audiometric records are available, comprising all groups, the following results were obtained:

Three-year-old cases—Just over 70% showed a maintained hearing improvement of over 11 decibels.

Two-year-old cases—73% showed a maintained hearing improvement of over 11 decibels.

A maintained hearing improvement of 11 decibels or more does not necessarily mean that the patient's hearing was maintained at the 30 decibel level. To my mind there can be no more difficult assessment of an operation result, for what improvement satisfies one patient does not necessarily satisfy another.

The fact that over 40 successful cases have had the operation performed on the other ear at their own request speaks volumes for its value.

REFERENCES

1 PASSE, E. R. G., and BLAINE, G. (1948) *Lancet* (ii), 651.
2 —— (1949) *J. Laryng. Otol.*, **63**, 495.

Mr. J. P. Monkhouse spoke of the difficulty of predicting results and said that he had obtained very marked improvement in some of the most advanced cases. These were often older people and the improvement seemed to last better than in some which might have been thought to be more favourable.

The assessment of results or of the value of a change of technique was necessarily a lengthy process and otologists should pool their knowledge and experience, but before they could do this, they must speak a common language. He felt that this meant the use of speech audiometry, since pure tone audiometry could err, sometimes suggesting a better and sometimes a worse hearing for words than was actually the case. However, as they had just heard, there were pitfalls in speech audiometry and a standard and reliable technique would have to be evolved.

The results at the Middlesex Hospital had been assessed on pure tone audiometry and the patient's own opinion had been entirely ignored.

Cases had been graded into "Very good"—over 35 decibels improvement; "Good"—25–35 decibels; "Moderate"—15–25 decibels; "Slight improvement"—5–15 decibels. Anything up to 5 decibels was considered as showing no change. The marking had been strict.

In the earliest series of 19 cases, in which a stopple was used, there had been an immediate improvement of some degree in 74% but now, after three years, only 16% retained any gain.

A series of 28 cases, without stopple but with a long fenestra and all two or more years since operation, showed an immediate improvement of 87%, falling after two years to 52%. The detailed figures were of interest: "Very good" 43% falling to 6%; "Good" 32% falling to 18%; "Moderate" 11% falling to 3%; "Slight improvement" 3% rising to 25%; "No change" 0% rising to 18%; and "Worse" 11% rising to 30%.

The following 14 cases operated upon more than eighteen months but less than two years ago showed approximately the same percentage (85%) of immediate improvement and to date 72% were still improved. Failure after a primary success seemed to occur around six months or at about eighteen months after operation, and since these cases had all passed the eighteen-month mark, he had hopes that they might show a better result than had the earlier series.

Mr. C. A. Hutchinson asked Mr. Cawthorne whether he had noticed any improvement in the hearing of the other ear after fenestration. The speaker noticed that using exactly the same audiometer at intervals of six months, a year and two years post-operatively, in a good case there appeared to be some improvement in the other ear.

He agreed as to a pink tympanic membrane being an index to a poor chance. Cases showing the "flamingo-pink" tinge did not do well with fenestration. He was interested to note that both Mr. Cawthorne and Mr. Garnett Passe referred to the need for an unobstructed foramen rotundum for a good result. When there was a poor result after what appeared to be a perfect technical procedure there might be some further improvement if a second fenestration was done through the promontory and covered with a flap of mucous membrane. He was experimenting along that line at present.

He did not use the same approach as Mr. Cawthorne. He agreed with Mr. Simson Hall and used the postero-superior approach, but whichever approach was used the technique inside was almost identical. Whether it was done pre-meatally or post-meatally one was faced with the bugbear of bleeding. One could cope with it up to a point by preliminary injection of the field with adrenaline saline. It was a great help, he found, to make use of continuous-flow saline adrenaline and small "postage stamps" of gelatin sponge; there were three sizes 1, 2 and 3; 3 was the most useful. One or more could be applied dry over an oozing area, left in place for twenty seconds when all the bleeding stops.

He would like to congratulate Mr. Cawthorne on his paper and admirable film.

Mr. A. Brownlie Smith said that he would have liked Mr. Cawthorne to have given some figures of the result of the operation according to the different age-groups. Otosclerosis was usually a more acute disease in the young and from his own cases he had found that the best and most permanent results were those obtained in older people where the disease had slowed down or stopped and where the bone regeneration was not so efficient as in younger people. He had found it difficult to decide whether to operate on young otosclerotics or not. He had a young girl of 16 under his care at present and he felt she might obtain a marked improvement in the hearing from the operation but, afterwards, be just as bad, if not worse, than before.

Dr. G. I. Henderson (*Dundee*) said that he had found that bleeding during operation had been considerably reduced by the type of anæsthesia used. The desired conditions had been obtained mainly by the intravenous injection of omnopon at the time the intratracheal tube was passed while light trilene was administered.

Mr. W. G. Scott-Brown advocated the use of a plastic or tantalum stopple and it was for that reason that he had sent all his cases to Air Commodore E. D. D. Dickson for the last six months for testing before and after operation. He had a small series of cases to record: in 1946 he operated on 20 cases and of these 4 had over 25 decibel improvement; 8 had over 15 decibels, and 5 had under 15 decibels; 3 remained the same or were worse. In 1947 there was a series of 21 cases; 7 obtained over 25 decibel improvement, 6 over 15 decibel improvement, and 5 under 15 decibel improvement—which did not give any very useful improvement. 3 were the same or made worse. The advantage of the stopple was that the operation was simplified and a fewer number of cases required reopening. He had only had to reopen 3 of the cases reported.

There was one interesting feature since he had used stopples with a larger hole through them. In cases with good hearing result there was practically no giddiness on touching the stopple. He asked Mr. Cawthorne for an explanation and he suggested that the displaced perilymph could "escape" up the canal through the stopple and so minimize the flow of perilymph along the canal.

Mr. R. Scott Stevenson said that no one had a greater admiration than himself for Mr. Cawthorne and his work, but he felt he had to ask one or two questions with regard to his paper. The first was about the criterion for operation. Looking at the audiograms that had been shown, he would say that the last 2 patients were cases of nerve deafness and to such patients he would say, "Go and get a hearing-aid and learn lip-reading". Hearing-aids and lip-reading were very helpful to such people, and it was wrong to persuade them to have a fenestration operation when the case was admitted to be so unfavourable. Otologists looked to Mr. Cawthorne for guidance on when to operate and in this paper they did not get it. He recognized Mr. Cawthorne's honesty of purpose, but if he operated on such patients, what were other people going to do? Mr. Cawthorne had started off by saying that the disease of otosclerosis was no longer obscure, but that was not really true. It was probably even more obscure to-day than it seemed to be before, and one did not know any more about the cause of otosclerosis to-day than was known one hundred years ago. Otologists must not be lured away by beautiful technique; it was always something to be suspicious of rather than to admire.

Mr. R. G. Macbeth said that Mr. Cawthorne had referred to his lack of experience of the Popper approach to this operation. In a series of about 100 cases the speaker had done 15 by the Popper approach. It looked very good in the pictures, it was very good in the post-mortem room, but when it was tried on the living it was a needlessly difficult operation to perform. Not only did the surgeon find himself mixed up with a plexus of veins in relation with the parotid fascia, but the access to the dome of the vestibule was restricted and he might have to become ambidextrous with the dental drill. The chance of post-operative scarring and stenosis was very much more marked than by the more traditional routes, and the chance of sepsis from the meatus seemed greater. It might be thought a little unfair to condemn the approach on a basis of 15 cases, but when the speaker reverted to the Lempert type of approach, he had been struck immediately by the fact that this was a much easier operation. The chorda tympani nerve was seen more readily by the Popper approach, but this seemed its only advantage.

Mr. F. McGuckin thought there might be some scientific interest in the audiometric recording of minor post-operative changes; but it would be well to realize frankly that improvements of the order of 5 or 10 decibels, perhaps even of 15 decibels, represented clinical failure from the viewpoint of the patient.

Mr. T. Cawthorne, in reply to the discussion, said he was interested in Mr. Garnett Passe's remarks and particularly in what he said about the round window. He had used the lead burr in a number of cases, but seeing, under the microscope, fragments of lead dropping into the perilymphatic space made him uneasy, so he had given it up.

Mr. Monkhouse and Mr. Brownlie Smith both brought out the point with which he entirely agreed, namely, that older cases did better. He was sure cases did better from the late thirties and forties onwards. He had had 4 cases which had been submitted to operation over the age of 60 and they had all done well. Unfortunately one must operate on some of the young people who have a rapidly progressing form of deafness but the results were sometimes disappointing. He had not analysed the results for different age-groups in this series.

Mr. Hutchinson asked about the question of improvement of hearing in the unoperated ear. He was particularly interested to hear that this was noticed in those patients whose hearing was much improved by operation. He thought it probable that when the ear not being tested was adequately masked, any apparent improvement would disappear.

With regard to what Mr. Scott Stevenson had said he hoped that he had not given the impression that he operated on every case he saw. He had agreed to operation in about 600 cases out of 1,100 cases of otosclerosis which he had seen during the past four years. Most of those classed as unsuitable decided against operation after they had realized the prospects of improvement. He assured the Section that the deafness in every case in the present series was, in his opinion, due primarily to otosclerosis.

It was quite true to say that otosclerosis was no longer an obscure disease. As was the case in many other diseases the cause was still not known, but the pathology was fully described. Moreover, the diagnosis of otosclerosis, except where it might be complicated by other otological disease, was not obscure, thanks to the constant clinical picture.

Owing to exigencies of space in the *Proceedings* the Honorary Editors are compelled to forgo publication of the following:

Oral Pathology in Children

By Professor J. BOYES
University of Durham

THOSE who devote themselves to the study of oral pathology do not recognize the division of their subject into the oral pathology of adults and the oral pathology of children, but the clinician is aware of certain advantages in this classification and it is from the point of view of a clinician that this brief survey is presented.

There are only a few occasions when the advice of the dental surgeon is sought in connexion with the *newborn*. I think all of us regard it as a red-letter day when we are asked to see that pleasant curiosity, the infant born with teeth. I never stand by the cot of one of these infants without wondering if I am in the presence of one who in later life will be a national figure, for Louis XIV, Mirabeau, the anatomist Broca and Curius the defeater of Pyrrhus, to mention only a few, showed this abnormality. The prematurely erupted teeth should be extracted. If left they ulcerate the under surface of the tongue, to say nothing of the mother's nipple. Recently such a patient came under my observation. The mother did not wish the teeth to be removed but within three weeks there was a lingual ulcer and the tongue had so pressed upon the teeth that they became loose and were ultimately picked out with dressing forceps. This is not always the clinical course and I recall a patient in whom the teeth remained firm and to cure the very severe ulceration which had developed the teeth were removed. I know of a family in which this abnormality is hereditary; three generations have shown the condition. Nobody nowadays regards this early eruption as a sign of congenital syphilis.

Another condition for which the pædiatrician seeks early dental help is *micrognathia*. Because the infant's jaw is so small the tongue is forced to occupy part of the pharyngeal space and there are signs of respiratory obstruction. The principle of treatment is obvious and accepted by all; the mandible must be brought forward. All are agreed that it is most convenient to do this by means of a submandibular sling attached over the head. There the unanimity ends for each dentist who treats these children devises his own appliance, as a reference to the literature shows. A recent suggestion is that the jaw should be kept forward by a weight acting over a pulley. This is claimed to be eminently successful but I believe that the ingenuity of most dentists can overcome the problem in a less drastic way.

In former days the dentist's help was sought in the very early treatment of *cleft palate* and within a few days of birth the infant was using a suckling plate. I wonder if the spread of the present trend, in one or two centres of cleft-palate surgery, to delay operation till a much later age than at present will revive the demand for this appliance. Recently three cases of submucous or occult cleft came under observation. In one the defect was in the bone, in the second it was at the junction of the hard and soft palate and in the third it was in the soft palate and ended in a bifid uvula. Clefts of the face usually conform to the lines of junction of the various facial processes which appear during development.

True congenital defects of the *tongue* are not common. In former days the fear for a tongue-tied infant was considerable. In the few cases I have observed where this abnormal frænum had been left uncut there seemed to be no ill-effects. In the main, like the palate the tongue develops from two lateral parts which grow medially and the organ is completed by a small central mass posteriorly derived from the tuberculum impar. Clefts appear along the lines of fusion and abnormality from a bifid tip to the tongue with two lobes is possible. Excessive development of the portion from the tuberculum impar gives rise to the so-called second tongue on the dorsum of the main organ.

The cause of these malformations and defects has up till now remained inadequately explained and the science of teratology has been in the background as far as active and popular research is concerned. However, Gregg's observation of the association of congenital defects, especially cataracts and heart deformities, with the mother having an attack of rubella during the first three months of pregnancy, has stimulated enquiries once again into these distressing and handicapping states.

In the first months of infancy children are particularly prone to bacterial infections and apart from congenital and hereditary lesions oral pathology in infants is largely the pathology of infection and inflammation.

Stomatitis is common, especially the generalized acute streptococcal or staphylococcal type, and of course thrush in debilitated children. Two ulcerated conditions of the palate have been specially named, Bednar's aphthæ (bilateral ulceration of the hard palate) and the pseudodiphtheria of Epstein. It is worth while recalling the normal appearance of the infant's palate with the clinical swellings—the epithelial pearls. *Salivary gland inflammation* in the newborn is a troublesome condition. Bony swelling of the mandible and other bones is seen in a condition that seems to have been observed more frequently recently, the cortical hyperostosis of bone. Osteomyelitis occurs every now and again and in infants it is characteristically in the maxilla. Serious complications can occur with this condition especially when the pus enters the orbit. Thanks to penicillin and sulphonamide the terrors of these infections are now rapidly passing away.

The dentist is usually troubled by *teething* only in his role as a family man. However, teething is important and various general manifestations such as colds, bronchitis, and running noses are common occurrences at this time. Local penicillin would be helpful for those children whose gums become ulcerated and inflamed. The ideal would appear to be a penicillin lollipop but so far I cannot get any of the manufacturers to make one. I have made lollipops by freezing penicillin solution flavoured with peppermint round a stick. They are quite pleasant to suck but they melt rather quickly once outside the refrigerator and so cannot be dispensed for out-patients except in vacuum jars—which is not at the moment economical.

When the teeth erupt they may be normal or they may show some abnormality of form or size or colour. In the last group one sees every now and again the child with yellow teeth who has had icterus neonatorum.

Dental caries is one of the commonest diseases of children but cannot be treated at length in such a survey as this. Let it suffice then in this connexion to mention the first carious lesion liable to appear: this is on the labial surface of the upper central incisors. I have seen a number of children with active caries in these teeth before they are a year old, and many children lose their incisor teeth before all the temporary teeth have erupted. Some children are wearing dentures at the age of 3 years. I had hoped that the recently advocated ammonium ion tooth powder was going to help these children but so far I have been disappointed in the results.

In the first year of life most of the *neoplasms* are congenital. The benign nævus type of tumour is probably the commonest—the hæmangioma and the lymphangioma. The congenital epulis is rare and its pathology is inconstant. In the recorded cases it appears to have been seen only in female children and the only case that I have seen was also in a little girl. A common gum swelling on the other hand is the eruption cyst which is readily diagnosed by its blue colour and clinical features.

In considering oral disease in older children it is perhaps easier to consider the subject in terms of symptomatology.

The condition of the *tongue* can be extremely helpful, for example the typical strawberry tongue in scarlet fever and the dry, coated tongue in gastro-intestinal upsets. In infants no fur appears on the tongue till the filiform papillæ appear; these are absent at birth. Parents are occasionally worried about their children should they show lingua geographica, the symptomless wandering areas of desquamation. Nicotinic acid in the age proportion

of the adult dose of 150 mg. daily will usually clear the tongue. It is to be remembered that anæmia and nutritional deficiencies occur in children and consequently the smooth tongue can be seen in young patients. Of the *gum enlargements* found in children, the endocrine gingivitis is encountered from time to time in patients during the period of puberty. Mouth breathing is a frequent cause of hyperplastic gingivitis. The idiopathic fibromatosis gingivæ is rarely seen but the hyperplasia associated with epanutin is becoming more common as its use in epilepsy is increased. Epileptics frequently have ulcerated tongues or show healed scars as the result of biting their tongues. Sublingual ulcers are met in whooping cough as a result of trauma to the underside of the tongue during sickness.

Oral ulcers in children are clinically similar to the lesions in adults. Aphthous ulcers occur frequently in children. In one baby of 2 years there was a familial element, and his brother, mother and maternal grandmother all suffered from recurrent aphthous ulceration. The antihistamines give good results in the majority of cases of the recurrent type.

Until a year and a half ago I always taught that *tuberculous ulceration* in the mouth was secondary to a focus elsewhere, usually in the chest. However, since then I have had cause to alter this dogmatic point of view for, during this period, three patients have attended the Newcastle-upon-Tyne Dental Hospital suffering from primary tuberculous ulceration in the mouth. All children were carefully examined by my colleague, Dr. F. J. Miller, and no other focus was seen radiologically or discovered clinically. Under treatment with streptomycin the ulcers healed completely.

The oral stigmata in congenital *syphilis* have been so fully described elsewhere that they do not require mention here but as members of this Section we should remember that it was at a meeting of the Odontological Society that Sir Jonathan Hutchinson read his famous paper describing for the first time the teeth which bear his name. (*Trans. Odont. Soc. Gt. Brit.* (1858) **2**, 95).

The commonest *swelling* of the jaw is the abscess. An abscess of the mandibular first molar occasionally progresses to osteomyelitis of the mandible. To-day penicillin has altered the whole outlook towards this disease. The abnormality of the lower jaw as the result of arrested development, or the bird-face of temporomandibular joint ankylosis will, I believe, gradually disappear from our clinical experience. As in adults so in children—cysts cause a centrally expanding tumour of the jaw. The dentigerous cyst is the commonest and it is surprising how frequently a badly depressed but vertically placed tooth will erupt into good position once the cyst has been opened up. The traumatic cyst is interesting, being without epithelial lining. It is the result of the irritation and resorption of an intra-osseous hæmatoma and to open it is to cure it.

The appearance radiologically of bone destruction not related to the apices of teeth usually means malignancy. The clinical signs and symptoms of the *malignant neoplasms* of mesoblastic origin are well known. In view of the variation in sensitivity to radiotherapy I believe a biopsy should be performed to ascertain the best line of treatment. Recently a clinical sarcoma was proved histologically to be a plasmocytoma and vanished under deep X-ray therapy. A girl aged 14 had a swelling in the palate related to a badly broken-down upper first molar. The diagnosis of abscess seemed obvious and there was an area of rarefaction on the radiograph. Ten days after extraction a biopsy was performed and the histological diagnosis was osteoclastoma.

Another clinical sign of some importance in children's mouths is the *exfoliation of teeth*, not the physiological shedding of milk teeth but the loosening and extrusion of otherwise healthy teeth. Pink disease is probably the first condition that comes to mind when this clinical sign is presented. As Sir John Fraser showed, Hand-Schüller-Christian disease is another. From the dental point of view the fatty substance can look very like pus when a collection of it is liberated by the extraction of the loose teeth. Sometimes severe Vincent's ulceration will destroy the supporting tissues with loosening and exfoliation of the teeth. In one girl the teeth loosened at the age of 12. The most severely affected teeth were almost without any bone support whatever. There was no explanation, local and general examinations were negative except for some swelling of the gum and chronic inflammation.

A word or two to finish this brief survey about three general conditions of great dental importance, hæmophilia, congenital and acquired heart disease and bronchiectasis. In all children in this group prevention is better than cure and they must have constant dental supervision. For the past two years I have kept a register of all patients in this group that come my way; a system of three-monthly recall operates and caries is kept under control and the oral hygiene is supervised. This is the logical dental approach for these diseases and the anxiety of extractions for children with hæmophilia and heart disease no longer arises.

An Unusual Case of Locked Jaw.—J. F. LOCKWOOD, L.R.C.P., M.R.C.S., L.D.S.

The case I wish to place on record concerns a healthy man, aged 34, who awoke one morning to find his mandible locked in the closed position, in which it remained for ten days.

There was no history of mandibular disease or injury, nor of any recent cuts or abrasions.

On examination : $\frac{--654321 \mid 12345-78}{87-54321 \mid 123-56--}$ were standing.

Considerable calculus and marginal gingivitis were present. $\overline{8}|$ was very carious. No signs of acute inflammation were visible.

Efforts, by the patient and by me, produced opening of not more than 5 mm. and were painful.

X-rays of the temporomandibular joints were normal and showed the condyles to be in their rightful positions. Dental X-rays also were normal.

I began to suspect that the condition might be an hysterical one, but somewhat callous tickling of the soft palate and posterior pharyngeal wall failed to produce any change.

Then I noticed the presence of inferior protrusion of a degree sufficient to allow the lower canines to act as fulcra and to give the lower incisors room to overclose.

Further questioning based on this observation clarified the course of events. The patient had a habit of sleeping on his face with his chin resting on his forearm.

On the night in question, during the muscular relaxation of sleep, this attitude must have exerted upward pressure on the symphysis menti in such a way as to elevate the lower incisors and depress the mandibular condyles. This allowed one or both of the intra-articular discs to drop forward in the joint, so that, on waking, the return of muscular tone had trapped the disc or discs and locked the mandible in the closed position.

Acting on this hypothesis, I insinuated a Mason's gag on each side of the mouth and, after warning the patient, exerted gradually increasing pressure. Suddenly resistance disappeared. There was an audible click and the patient's hand flew to his left temporomandibular joint.

The following day the jaw was a little stiff first thing but the patient was able to enjoy his lunch. No further treatment was given.

DISCUSSION ON FAINTS AND FITS

Sir Charles Symonds: The symptom common to fits and faints is loss of consciousness which, by definition, is of rapid onset and brief duration. By definition again the word "faint" commonly implies a loss of consciousness due to a temporary failure of the cerebral circulation of postural or reflex causation, not the result of heart disease. This definition would exclude from our consideration attacks caused by heart block or other cardiac disorder, and also those due to hypoglycæmia.

The word "fit" may be used to indicate that the loss of consciousness is attended by convulsions, or in a larger sense to include an attack or seizure of any kind that is epileptic. The wider meaning is clearly more appropriate. When, therefore, I speak of fits I shall mean epileptic attacks. The definition of epilepsy is not easy, but Hughlings Jackson's physiological concept of "occasional, sudden, excessive, rapid, and local discharges of grey matter" will serve—perhaps as well to-day as when it was first written. The confirmation of this hypothesis by the E.E.G. is indeed remarkable.

Having regard to these definitions there appears to be a distinction between fit and faint of fundamental importance. In the fit the disorder of function is at the onset local: it is somewhere—and it may be almost anywhere—*in* the brain. It is therefore to be expected that the symptoms of a fit will show great variety, depending upon the parts in which the discharge arises. That this is abundantly true is confirmed by clinical experience. The number of epileptic variants is legion. In the differential diagnosis it is often possible in a moment to decide that an attack is a fit, not a faint, by reason of its local sign, generally the aura described by the patient, sometimes the observation by others of particular movements or localized spasm. But there are many varieties of epileptic attack in which there is no clinical evidence of local origin, or at any rate none which distinguishes the attack absolutely from a faint. The aura is present in little more than a half of the attacks of idiopathic epilepsy. The spread of the discharge in a convulsive attack is often so rapid that the movements are at once generalized, and, even more important, the epileptic discharge may begin in those parts of the central nervous system which are also involved in fainting, a subject to which I shall return later.

By contrast with the local origin of the epileptic attack there is in a faint involvement of the brain as a whole. This does not, of course, mean that the brain is equally affected in all its parts at the same time by a particular degree of anoxia. There seems to be an order of susceptibility so that some parts give out before others. The retina, for example, fails early and so do the centres for postural tone. Dimness of vision and loss of equilibrium, therefore, happen in a faint before loss of consciousness. Thus in a faint, if the onset of anoxia is not too abrupt, there is a certain order of lost function which is characteristic. This is true of most faints but there are striking exceptions. In the disorders known as postural hypotension and carotid sinus syncope, which both fall within my definition, the onset of the faint may be abrupt, and this is also true in some cases of reflex—I mean emotional—fainting. The sudden onset of pallor, unconsciousness and falling then closely resembles the symptoms of a minor epileptic attack. The resemblance is even more striking when a faint is attended by convulsive movements. It is well known that these occur when cerebral anoxia is of sufficient degree and duration. They were recorded in 7% of a series of 362 faints in blood donors, whose symptoms were analysed in a Medical Research Council Report. There is no doubt that in a faint of reflex origin ventricular standstill may occur and when this happens loss of consciousness ensues within 5 to 10 seconds, and if the heart stops for 15 or 20 seconds there are convulsive movements.

This happened in a patient whose case I have reported elsewhere, a young man who was liable to faint at the sight or thought of illness or even when examined by a doctor. While serving in the Army he was referred to Captain Michael Ashby with the diagnosis of epilepsy confidently made by a medical officer who had witnessed an attack. While Captain Ashby was examining the patient he found that his pulse was beating about once in 3 seconds. I quote verbatim his note on what followed. "I had only time to take three more beats when it stopped completely, confirmed by auscultation, for 45 seconds, during which he had a fit, rolling eyes, rigidity, and a few convulsive movements. The pulse stopped before the fit by about 10 seconds." This was an extraordinarily complete observation of cardiac standstill in a faint. The electrocardiogram in this case was normal, and in a subsequent attack induced by Dr. Denis Williams while an E.E.G. was recorded there was no evidence of epileptic activity, so that I do not think there can be any doubt that this man's attacks were faints.

To return now to the subject of epileptic variants, there is little doubt that the discharge may be localized in those parts of the brain, wherever they may be, upon which the state of consciousness depends. The epileptic attack often consists of nothing else but a loss or disturbance of consciousness. When together with this loss there is loss of postural tone with falling, the symptoms of the attack are indistinguishable from those of a very sudden faint. But if there is loss of consciousness without falling I believe we are right in supposing the attack to be epileptic, for in a faint the two go together.

Other epileptic variants which may resemble faints are those which have their origin in visceral centres. There is little to be said on this subject which has not already been stated by Kinnier Wilson (1928) in his classic paper. Pallor, nausea, palpitation, and dizziness separately or in combination may usher in an epileptic attack, or may occur as its sole manifestations.

A woman aged 20 was referred to me for attacks which had begun three years before. She would suddenly feel sick and dizzy, with buzzing in her ears and inability to hear clearly. If possible she would lie down for a minute or two and would then feel quite well. She had never fallen and was positive that she did not lose her senses. Attacks had been witnessed by her parents. In one of them she was driving a car and said to her father "Oh, Daddy take the wheel". She turned pale and had recovered in a minute or two. On another occasion she was in the garden with her mother, said she felt faint, lay down on the grass for a minute, and then said she was all right. Later, however, she had an attack while alone in her bedroom, beginning in exactly the same way. She went to lie down, but lost her senses and was found unrousable twenty-five minutes later, having bitten her tongue and passed water. Enquiry revealed that for the past four years about three times a year she had woken in the morning with a headache, a sore tongue and sometimes a wet bed, feeling as if she had had a nightmare. Her subsequent story has been that of epileptic attacks, almost but not quite controlled by phenobarbitone and epanutin.

I think it fairly certain that the little attacks, which had been diagnosed as faints, were, in fact, epileptic.

One cannot mention visceral epileptic variants without referring to what Gowers (1907) called vaso-vagal attacks, a designation which has been widely misunderstood, mainly because the term vaso-vagal attack was much later used by Sir Thomas Lewis to describe fainting. Gowers used it for prolonged attacks comprising symptoms which he thought must be referable to a disturbance in the medullary centres. "The attacks", he states, "are never really brief, they seldom last less than ten minutes and more often continue for half an hour or more." The symptoms, according to Gowers, might include epigastric discomfort, respiratory distress, substernal discomfort, coldness, pallor and often a sense of impending death. These attacks are, I believe, quite rare and are not to be confused with so-called anxiety attacks. Kinnier Wilson in the paper already mentioned suggested that they were epileptic variants of visceral type, arguing that their extended nature was no insuperable obstacle in the way of acceptance of the hypothesis.

I have had under my care at nospital a woman who had attacks of this kind at infrequent intervals occurring during the day and lasting an hour, each being followed during the subsequent night by a major epileptic attack in her sleep.

It is of course the duration of vaso-vagal attacks which makes them unlike epilepsy but as an example of the manner in which a single visceral symptom of epilepsy may vary in duration I take substernal pain.

A man began to have attacks at the age of 29 and had half a dozen in the next five years. There was a sudden onset of what was described as a vice-like pain between chest and back, which rapidly increased in severity and after a few seconds he became unconscious for five minutes. In one attack he bit his tongue. Dr. Denis Williams on two occasions found an abnormality in the E.E.G. indicating a long-standing benign lesion of the left hemisphere.

A woman aged 37, who had previously suffered from migraine, had her first epileptic attack while at a theatre. It was preceded for an hour by a pain in her chest like indigestion. She then told her husband she was going to faint and had a fit in which she bit her tongue and passed water. On a subsequent occasion she experienced substernal pain all day, then felt a sudden rush from her stomach to her head (an epigastric aura) and had a fit.

The transition from this case to the next, which is an example of Gowers' vaso-vagal attacks, is I think easily followed.

A married woman, aged 25, began to have infrequent and causeless attacks which were all of the same kind. There was a sudden onset of substernal pain like toothache, everything started to swim, and her head sweated. She lay down and remained in this state (the substernal pain continuing) for about two hours with a feeling as if she were going to die. There were two more episodes of this kind in the next three months. Finally she had a more serious attack which brought her to see me. She was on holiday taking the air before breakfast when there was a sudden onset of substernal pain with sweating at the temples and sound coming and going. She just had time to say to her husband "Look out" before she fell unconscious. He stated that she was pale with stertorous breathing, stiff for the first quarter of a minute, them limp, and remained unresponsive for five minutes. She was confused for ten minutes afterwards and had no memory of being carried up to bed. After she recovered her senses she continued to have substernal pain for two hours and during this period felt giddy if she attempted to sit up. Neither I nor any of my colleagues could find anything wrong with this woman. E.C.G., E.E.G., fasting blood sugar, blood sugar curve, response of pulse-rate and blood pressure to posture and effort were all normal.

This has been a digression from the main theme of our discussion. Vaso-vagal attacks are not faints, nor are they in any ordinary sense fits, but the observations which I have put forward support Kinnier Wilson's argument that they may be epileptic.

Perhaps the most important distinction between faint and fit is the setting of the attack. Faints very rarely occur except in the erect posture. If an attack occurs after long unaccustomed standing, or as the result of sudden emotion or pain, in a hot and stuffy atmosphere, or after loss of blood, it may be presumed to be a faint unless there is evidence to the contrary. If it occurs without any of these causes it is probably a fit. Yet again, however, the distinction is imperfect. Epileptic attacks may be precipitated by various causes of which emotion is one. The malaise of infection may be another. In the following case both precipitants were evident.

The patient was a man of 61, whom I saw for an entirely different complaint, and the details which follow were obtained from his past history. He had as he said "fainted" on many occasions. The first was in his teens when he was taken to the doctor with influenza, the second at 19 after a cycle accident. He was not injured, but very much upset, and lost his senses suddenly fifteen minutes later. The next occasion was a year afterwards when he went to have a tooth out, and, feeling, as he said, in a blue funk, lost his senses and fell before getting into the dentist's chair. In this attack he passed urine. There was a similar episode at the dentist's a year later. Again he passed water. There were no more attacks precipitated by emotion, but on about a dozen occasions he had fainted at the onset of a febrile illness, influenza or bronchitis. The sequence was always the same. He would begin to yawn and continue yawning for ten to twenty minutes. If he could keep walking about this might end without further incident, but if he gave way and sat down his vision would suddenly become grey and he would lose his senses for a minute. In almost all these attacks he passed urine.

These attacks, I believe, were epileptic for two reasons. The first is the occurrence of involuntary micturition in nearly all the attacks. This may occur in a faint if the bladder happens to be full at the time, but its regular occurrence always suggests an epileptic discharge involving the centres for micturition. The second reason is the prodromal yawning, recognized by Gowers (1901) and again by Kinnier Wilson (1928) as a precursor of epileptic attacks. I have several examples of this in my own notes of undoubted epileptics.

There is next to be considered a rare but important group of patients who begin by having attacks in childhood or adolescence which we diagnose confidently as faints, but who go on to have attacks which we are sure are epileptic. The earlier attacks have the usual causes for a faint, but the liability appears excessive, the attacks are more frequent than usual and continue to a later age and when they have continued long enough we are not altogether surprised when we are confronted with the story of an attack this time without cause and characteristic of epilepsy. In these cases then we observe excessive liability to fainting followed by an excessive liability to epilepsy. The word excessive may be equally applied to both. Anyone may faint or have a fit with sufficient cause. Why do some persons have faints or fits with so little cause or no apparent cause? The answer in the case of the epileptic is that there are nervous centres which are unstable. This is the trigger mechanism for the attack. Of the causes that operate to pull the trigger we know very little. In the case of the fainter on the other hand we know a good deal about the causes that pull the trigger, and we know that when the trigger is pulled there is bradycardia or fall of blood pressure to explain the symptoms that follow. But where is the trigger itself? Probably in the central nervous system. Fainting in response to emotion clearly suggests this localization. Again in a faint which results from prolonged or unaccustomed standing what is it that gives way? Surely the reflex mechanisms responsible for maintenance of heart-rate and blood pressure, and where are these except in the central nervous system? In the syndrome of postural hypotension, which provides the extreme example of postural fainting, there is a good deal of evidence for the existence of a trigger mechanism at or near the hypothalamus (East and

Brigden, 1946). It seems probable, therefore, that for faints as well as fits an essential link in the chain of causation is an unstable nervous mechanism. If this be so it would not be surprising if we sometimes found both kinds of instability present in the same person. Nor I think would it be surprising to find that with the passage of time the instability responsible for fainting became less and that responsible for epilepsy greater. This kind of thing sometimes happens in persons who have migraine in their youth and as they grow older exchange it for epilepsy.

The carotid sinus syndrome is also of interest in relation to the occurrence of faints and fits in the same person. In this malady pressure upon the sinus, according to Ferris and others (1935), may produce faints, with bradycardia or fall of blood pressure sufficiently abrupt to cause loss of consciousness and sometimes convulsions: or it may cause these symptoms without any adequate cardiovascular derangement to explain them. Thus it would appear that the specific stimulus in this syndrome may produce either reflex fainting or reflex epilepsy.

The general trend of these remarks has been towards the conclusions, first, that there is no absolute means of distinguishing between a fit and a faint unless the attack can be observed in detail with estimations of pulse-rate and blood pressure before and during the episode, and second, that even though fits and faints may be clinically distinguishable they are closely related in their dependence upon the instability of nervous mechanisms.

Dr. Denis Williams: "Familiar as fainting is, adequately as we seem to know it, there is much in it that we do not know. Our knowledge is enough to obscure our ignorance. The most obtrusive feature of complete cardiac syncope is the loss of consciousness which results, evidently due to the failure of the action of the heart which precedes and attends it. But the loss cannot be the direct effect of the cardiac failure, because consciousness is not the result of the circulation of the blood. To say this is to state an obvious truism, for the two are totally different in nature. The loss must be immediately due to a state of the nerve elements of the brain produced by the change in the circulation. We are apt to overlook this when we think of the process of fainting, but its recognition is of great importance because consciousness may be lost from other causes. It is the most common feature of the epileptic seizure. Not long ago it was thought to be a constant feature; without such loss an attack was said not to be epileptic. We now know that minor attacks are common in which consciousness is only dimmed: sometimes hardly a ruffle on its surface attends the sensation which constitutes the slightest form of attack. Still, in the pronounced form of each condition, in fainting and in epilepsy, loss of consciousness is a dominant feature. The fact is of practical importance in diagnosis, because it often makes their distinction difficult, and sometimes causes a mistake. For another reason, also, the loss of consciousness is important. We do not know in either malady the nature of the process in the nerve elements on which the symptom depends. We do not know whether it is the same in the two or is different. If we can trace any relation between the affections it will constitute some evidence on the question, evidence at least suggestive. For this reason also the study of fainting in relation to epilepsy is important."

Those words were written by Sir William Gowers over forty years ago, and they make it clear that we are discussing the problem in the same kind of way to-day as he did then.

Sir Charles Symonds has suggested that there may be a common link between epilepsy and syncope, although a precise distinction can normally be made between the two conditions upon clinical grounds. In considering any relationship between the two, it is of the utmost importance to keep such a distinction clear, for it is all too easy by elision to recognize a faint as a fit, and vice versa, and so seem to establish a relationship in any one case which does not, in fact, exist. Any experimental study of the relationship between epilepsy and fainting must be based on the certain recognition of an epileptic attack and a fainting attack as entities, and it is because of the failure to do so that so much work must be discarded. The criteria that Sir Charles Symonds has laid down are those which are readily acceptable to most of us, and such criteria should be employed in any experimental or statistical survey of the subject.

Kershman (1949) considered the relationship of "Syncope and Seizures". He took 114 patients who had a history of syncopal attacks or similar episodes without loss of consciousness. All of them had abnormal electroencephalograms between attacks but none of them had had a definite convulsive seizure. 65% had a diffuse dysrhythmia in the E.E.G. and Kershman concluded that "the form of the pathological E.E.G. abnormality and the character of the spells suggested a subcortical and probably hypothalamic origin for the attacks". He concluded that these "syncopal spells" were "a mild form of idiopathic epilepsy" and stated that "these spells were essentially the same as the vagal and vaso-vagal attacks described by Gowers, and the E.E.G. disturbances indicate that they are fundamentally epileptic in character".

At first glance all this might suggest that syncope is, as Kershman has suggested, a special if mild form of epilepsy. But the difficulty is that many of the cases included in his series clearly had epilepsy. Consider the first of his illustrative cases, that of a man who had an attack of unconsciousness while at breakfast, in which he suddenly felt a choking sensation, stood up and fell unconscious. He had urinary incontinence and recovered fifteen minutes later, weak and dizzy. In his next attack he was sitting, he had twitching of the lips and he was again unconscious. There is no doubt that this man was suffering from epilepsy and the absence of major convulsive movements does not in any way influence this fact.

This recent paper is quoted to emphasize the fact that no relationship between syncope and epilepsy must be claimed upon the results of statistical or experimental work which does not keep a clear distinction between loss of consciousness resulting from a change in cerebral blood flow (syncope) and that resulting from a primary change in cerebral activity (epilepsy). The clinical basis for this distinction is real.

Keeping clear the fact that there are, on clinical grounds, as well as upon the mechanisms responsible, distinctive differences between fits and faints, I would like to consider the evidences for a common bond between them. There are forms of syncope in which the mechanism of the loss of consciousness is so evident that it is hardly profitable to wonder whether an obscure cerebral mechanism is at work. Such are, for instance, the attacks of orthostatic hypotension resulting in loss of consciousness. There are others, however, in which there is a much closer affinity to epilepsy. I refer to reflex syncope caused by highly specific stimuli, often emotional in their background. The pattern of this disturbance is similar to that of some instances of so-called reflex epilepsy. We have already heard that habitual syncope and epilepsy may co-exist in the same patient, but when reflex syncope is considered the relationship between faints and fits occurring in the same subject may be close. The following are two cases which clearly illustrate this relationship.

Case 1.—An army officer aged 42 was undergoing dental treatment. 1% novocain had been injected, there was no pain and no apprehension. The dental surgeon said the patient suddenly went rigid, his pupils dilated, his eyes were open and he went into a tonic-clonic convulsion, with deviation of the head and body to the left. The convulsions lasted for 5 seconds, then he seemed normal. The patient said he suddenly felt ill, giddy, sweated profusely and then remembered no more until he found himself with his head in a basin. He was confused at that time. Afterwards he was cold and clammy, and the surgeon said that his pulse was thready. Important points are that the subject experienced no apprehension, or pain, that he was half lying throughout, and that the experience of the symptoms of fainting was momentary.

His past history showed that he had had the following kinds of attacks:

(1) In bed just before sleeping, about once a week he had a feeling of apprehension, thumping in the head, pounding of the heart, a hot clammy sensation and a feeling of pins and needles throughout the body. This disturbance seemed to last five minutes. It was never associated with loss of consciousness, incontinence or movement.

(2) In the daytime on sudden bending and rising he had typical postural hypotension with loss of consciousness.

(3) He had had repeated attacks of loss of consciousness in response to the sight of blood, accidents, or bomb casualties.

(4) On hot days, once or twice each summer, he had had attacks of unconsciousness which from the description were syncopal. The symptoms were similar to those of his attacks of orthostatic syncope, but the course of events was more rapid.

His only brother, a leader of a heavy rescue squad in the Civil Defence Services in London during the war, had never been upset by all kinds of horrible sights. Traumatic amputation of a finger did not greatly disturb him. He had lupus of the face and had to make frequent visits to hospital. He always had to be accompanied for treatment, because when he smelt the "smell of a hospital" he would fall to the ground unconscious with only the briefest warning. He might have time to say "I feel funny" then would fall, often hurting himself. He would have a tonic-clonic fit and be confused for a few minutes afterwards. He had never lost consciousness or even felt faint in response to any other stimulus.

The patient was normal on full examination. The E.C.G. and E.E.G. were both normal. Mechanical stimulation of the carotid sinus failed to produce any symptoms.

Here then is an example of a man having orthostatic and reflex syncope, hypnagogic disturbances and epileptic attacks in response to special circumstances, with a family history of epilepsy in response to a highly specific situation.

Case 2.—A young man of 19 hurt his hand slightly in machinery. He was having it dressed by a nurse when he suddenly fell off the chair in a tonic-clonic fit, which the nurse witnessed in detail. He was confused afterwards. He was not pale before the attack and he said he felt no great pain or apprehension while the wound was being dressed.

His past history showed that he was a high-grade defective, three years behind his age, whose physical development was normal. He had had no convulsions in infancy. When 8 he had a tonic-clonic attack after he had cut his finger, and after that he had six attacks at irregular intervals, each precipitated by sight of blood or injury to himself. In each he went pale then blue, fell to the ground and had convulsive movements. In one he was incontinent. He had no attacks of any sort in any other circumstances.

His mother, who was unstable emotionally, had periods of lack of emotional control when frustrated. At the height of her histrionic anger she would suddenly fall down, become cyanosed and have a tonic-clonic fit of short duration. She was usually incontinent in these attacks. The father, a brother and a sister were normal.

On examination, both the patient and his mother were normal. Their E.E.G.s were normal. In this case there was a maternal history of epilepsy in response to emotion, in a boy who had syncopal and epileptic attacks after physical injury.

There are innumerable instances of the presence of syncope and epilepsy in the same person, so that the point need not be stressed. The difficulty is to explain *why* the conditions should exist, and there are very many reasons why it is an over-simplification, and indeed a mistake, to presume that syncope is a minor and special form of epilepsy, as some would wish. It must be recalled that there are many cardiological causes of loss of consciousness, in which the mechanism at fault leads to a fall in cerebral blood pressure. For these such a point of view is clearly untenable.

I would now like to examine a small piece of evidence upon the nature of the common bond between the tendency to faint and the tendency to have fits. The electroencephalograms of four groups of subjects were examined. These groups were made up of large numbers of comparable cases, as in Table I. They comprised: (1) Patients referred for opinion who had had more than one fainting attack. These attacks, from the clinical description given and from the circumstances in which they had occurred, were, in my opinion, faints. In all there had been a fairly long period in which the patient was able to say to himself "I feel faint". This sense of impending loss of consciousness seems to be common to all but the most rapid forms of fainting (such as the Stokes-Adams attack). During this time there was usually a story of pallor, often sweating, coldness, and sometimes nausea. The patient often sought support, and if he failed to find it or to sit down, lost consciousness. In all these cases consciousness was lost. Whether or not convulsive movements followed such a chain of events was unimportant, for an epileptic attack often follows cerebral ischæmia. In none of these patients had there been a story of fits, however brief, which were not heralded by the symptoms of syncope or the circumstances which give rise to syncope.

(2) Patients with *grand mal* epilepsy, for which no cause had been found, and in whom fainting has not taken place—idiopathic epilepsy.

(3) Patients with a similar story in whom a head injury was thought to have been responsible—traumatic epilepsy.

(4) Normal men and women who had never lost consciousness.

All the subjects were adults, all serving in the Forces, and all were otherwise normal.

The electroencephalograms were divided upon (1) the existence of generalized abnormality of any kind, which placed the records beyond the limits of normal, which excluded at least 12% of the normal population (the standards employed have been described before, Williams, 1941), and (2) upon the presence of runs of abnormal fast waves (Figs. 1 and 2) in both frontal lobes. These disturbances were specially picked out for study because they had so often been seen to occur in patients in whom I had no doubt that syncope and not epilepsy was the correct diagnosis, upon the criteria already outlined.

The results of this division of the cases is shown in Table I.

TABLE I

		Electroencephalogram				
			Non-specific abnormality		Episodes of fast activity	
Diagnosis	No.	No.	%	No.	%
Syncope	68	21	31	13	19
Idiopathic *grand mal* ..	94	54	57	21	22
Traumatic epilepsy ..	68	49	72	14	21
Normal	70	11	16	3	4

FIG. 1.—Episodes of fast rhythms arising in both frontal lobes in a patient with repeated faints. The electroencephalogram is otherwise normal.

FIG. 2.—A normal electroencephalogram, similar to that in Fig. 1 except that there are no abnormal fast rhythms in the frontal lobes.

This shows that there is a significant increase in abnormality from normals to syncope and the epileptics, but it also shows that the proportion of those showing abnormal fast activity in the frontal lobes is the same in all the abnormal groups (about 20%), while it is only 4% in the normals.

Because of these results, members of the hospital staff were asked confidentially if they had ever had any attacks of any sort, and in 16 instances the subject had fainted more than once in his life, but had always been considered to be normal. None had had epileptic attacks. This small group of 16 otherwise normal fainters were in all other respects exactly comparable to the normal control group, none of whom had fainted more than once. In Table II it will be seen that the proportion with generalized dysrhythmia was the same in the two groups, whereas the proportion showing abnormal frontal fast activity was significantly higher in the small group of "fainters".

TABLE II

		Electroencephalogram				
			Non-specific abnormality		Episodes of fast activity	
Normal subjects	No.	No.	%	No.	%
Fainters	16	2	12·5	7	43·7
Others	70	11	15·7	3	4·3

Disturbances of an "epileptic" kind are probably absent from the subjects who faint in this series because of the care which had been taken to divide epilepsy from syncope, but even so there is an episodic disturbance of the kind so often seen in epileptics—particularly those suffering from *grand mal*—occurring in a proportion of people who faint, even though they felt normal at the time of the recording. It would be wrong to assume that this finding indicates that syncope and epilepsy are the same condition but it must indicate that a common factor exists in the mechanism of the two conditions.

The clinical experiences which have been recounted both by Sir Charles Symonds and myself would support the hypothesis that there is such a common factor, and this factor must surely reside in the cerebral hemispheres. It may well be that it consists of the kind of reaction of the hemispheres—the failure to maintain normal activity—in response to deleterious circumstances, whether these consist in changes arising in the hemispheres themselves or elsewhere in the body. That is to say that consciousness is more readily lost in these than in other subjects whether the cause is a fall in blood pressure or an abnormal discharge of neuronal activity in the brain. Certainly in epilepsy some people lose consciousness whenever an epileptic discharge occurs in the E.E.G., while others have numerous "larval attacks" in the E.E.G. without loss of consciousness (Williams, 1950). Certainly also in syncope some people lose consciousness more readily than others with a similar rate and extent of fall in blood pressure. There are at least three mechanisms responsible for the faint:

(1) The special response of the individual to specific circumstance, which may sometimes be a conditioned response to a previously emotional situation.

(2) The resulting disturbance in the cardiovascular regulating mechanisms.

(3) The consequent disturbance in cerebral activity, with loss of consciousness and other changes.

It is in the hemispheres that syncope and epilepsy have common ground, and the similar response of the hemispheres to different abnormal states may well be reflected in the common features seen in the E.E.G.

SUMMARY

Evidence is produced to support the view that one of the factors common to faints and fits is the failure o the individual to maintain consciousness in special circumstances. The view is expressed that although syncope and epilepsy may co-exist in the same family or the same individual, syncope is not a special form of epilepsy. The clinical and experimental knowledge that we have lends support to the view that, although the mechanisms responsible for faints and fits are different, they may occur in the same person because of a common factor in the hemispheres, reflected in the E.E.G. This factor may simply relate to a failure to maintain consciousness under the conditions which exist in the two disorders.

Dr. Maurice Campbell: The identical word, syncope, is used for trivial fainting attacks and for a manner of death, and should, therefore, be banished from scientific discussion. It might be useful if it was recognized that syncope meant a sudden loss, and fainting a gradual loss of consciousness, but there is no such agreement and it would at present be wrong because syncope is by definition (O.E.D.) "a failure of the heart's action, resulting in loss of consciousness or sometimes in death". Fits are, of course, more often of cerebral origin, but not always: if loss of consciousness from anoxæmia lasts more than a certain time, the familiar sequence of events seen in any epileptiform attack will follow.

More accurate knowledge of attacks of unconsciousness will not be gained without more accurate descriptions and more precise terminology. The speed with which consciousness is lost is a fundamental distinction; and I suggest that the word tachy-apsychia should be used for sudden loss of consciousness, seen characteristically in most Stokes-Adams attacks or in epilepsy, and brady-apsychia for gradual loss of consciousness seen characteristically in most fainting attacks in young people. I am indebted to Mr. E. L. York of New College, Oxford, for the use of these words.

Loss of consciousness concerns the physiologist and neurologist even more than the cardiologist; but there is, perhaps, more knowledge of the provoking mechanism of unconsciousness in disorders of the heart than of the nervous system. The common factor in the former group is the production of cerebral anoxæmia—whether by change of rhythm, including ventricular standstill as in many Stokes-Adams attacks; by standstill of the heart as in a few fainting attacks, or during anæsthetics; by the combination of a slow heart and a fall of blood pressure or by one of these alone, as in most cases of fainting and of the carotid sinus syndrome; or by temporary arrest of the cerebral circulation by venous stasis or difficulty in auricular filling during violent spasms of coughing or after pulmonary embolism.

Broadly speaking, these various cardiovascular causes—and there are many more—can be divided into those where the cerebral circulation is arrested, often but not necessarily, by cardiac or ventricular standstill, and those where it is diminished (as in the severe fall of blood pressure after a large cardiac infarct or with a very rapid paroxysmal tachycardia) when the unconsciousness will generally be gradual.

As a rule, therefore, tachy-apsychia will mean sudden arrest, and brady-apsychia a gradual diminution of the cerebral circulation: there are, however exceptions, and of course, tachy-apsychia is often cerebral in origin. With arrest of the circulation there is greater danger of the heart failing to start again and so tachy-apsychia has, in general, a much graver prognosis than brady-apsychia.

A patient who has been unconscious can, as a rule, give the physician no direct indication as to whether the cause was cardiac or cerebral, and the decision may be difficult and may call for much knowledge and experience: the symptoms produced in either may be almost identical. It is, in particular, essential to be on familiar terms with epilepsy, in both its major and minor forms.

The duration of unconsciousness is of great importance in this connexion. A short attack, and this means one lasting less than two or perhaps five minutes, may be either cardiac or cerebral in origin. A long attack, lasting more than five or ten minutes, must be wholly or partly cerebral—partly when a short cardiac arrest starts the loss and produces anoxæmic changes in the cerebral cortex that prolong the unconsciousness.

Standstill of the heart or of the ventricle for from 5–10 seconds causes sudden loss of consciousness. Arrest of the cerebral circulation for from 5–10 seconds by a pressure cuff round the neck (Rossen *et al.*, 1943) causes sudden loss of consciousness, so this is further evidence that both act in the same way. Rossen *et al.* fixed a cuff round the neck that could be inflated to a pressure of 600 mm. Hg. In normal young men fixation of the eyeballs and blurring of vision were the first signs, nearly always within 5–7 sec. Loss of consciousness followed 1 sec. later, and the cuff was then released. Mild generalized convulsions followed but only lasted 6–8 sec. Consciousness was regained 4–10 sec. after the cuff was released. Longer periods of arrest of the cerebral circulation up to 100 sec. were produced in 11 patients with schizophrenia; all regained consciousness in 30–40 sec. and there were no after-effects.

In unconsciousness due to cerebral anoxæmia spasmodic movements or fits are dependent on the depth and duration of unconsciousness and not on its cause: they may, therefore, occur in attacks of all sorts. They follow 15–20 sec. after the arrest of circulation.

Arrest of the cerebral circulation for two minutes by standstill of the heart in disease or during anæsthesia or for 100 sec. in experiments on man is compatible with perfect recovery.

Standstill of the heart for 5 minutes is generally permanent, i.e. the patient is dead. In the rare cases where the heart starts again after longer than this, anoxæmia will have caused irreversible damage to the brain, especially to the cortex; and the first sign of this will often

be a longer period of unconsciousness. Where the cerebral arteries are diseased as in many cardiac cases and most Stokes-Adams attacks, a shorter period than five minutes may produce cerebral damage from which it is not possible to recover.

Standstill of the heart for more than two but less than five minutes will produce cerebral damage from which it may be possible to make a perfect recovery. The first sign of this cerebral damage may be a more prolonged period of unconsciousness. This means that even in a cardiac case that has been unconscious for many minutes, it is of great prognostic value to know when the circulation returns, i.e. when the heart starts beating. Ultimately this period of between two to five minutes may be defined more precisely though there will always be great danger about recovery in such cases. In clinical records of heart standstill periods of from 20 to 80 sec. are not often exceeded and these are well within the limits of complete recovery.

Table I shows the variety of conditions to be remembered and indicates whether tachy-apsychia or brady-apsychia is likely to be found.

TABLE I.—CARDIAC CAUSES OF LOSS OF CONSCIOUSNESS

I.—Standstill of heart, including long sino-auricular block. *Tachy-apsychia* if not preceded by IIA.
- A. Neurogenic (vagal)
  - (1) with normal heart.
  - (2) with heart disease.
- B. Myogenic, with heart disease.
- C. Anæsthesia.

II.—Slowing of heart with fall of B.P. *Brady-apsychia.*
- A. *Fainting attacks.*
- B. Carotid sinus syndrome.

A and B always neurogenic but may occur with heart disease.
- C. Postural hypotension
- D. Severe hæmorrhage } Fall of blood pressure only.

III.—Ventricular standstill. *Tachy-apsychia.*
- A. *Stokes-Adams attacks* (one form) (difficult if block paroxysmal). Always with heart disease.
- B. Neurogenic cases without previous heart block.

IV.—Tachycardia with changes of rhythm.
- A. Arrest of circulation. *Tachy-apsychia.*
  - (1) Paroxysmal ventricular fibrillation.
  - (2) Paroxysmal ventricular tachycardia.

  If with heart block 1 and 2 are *Stokes-Adams* attacks. And rarely from 3, 4 or 5 below.
- B. With slowing of circulation. *Brady-apsychia.*

  Some cases of 2 above.
  - (3) 1 : 1 auricular flutter.
  - (4) Onset of auricular fibrillation.*
  - (5) Paroxysmal auricular fibrillation or flutter.*
  - (6) Paroxysmal supraventricular tachycardia.*
  - (7) Repeated extrasystoles.*

* Only in those specially prone to fainting.

V.—Failure of the left ventricle.
- A. With cardiac infarction (which also causes other varieties).
- B. With angina pectoris.
- C. With aortic stenosis. Often with exertion and of serious import.
- D. With aortic regurgitation. Not serious unless syphilitic.
- E. With acute pulmonary œdema.

VI.—Failure to fill the left auricle.
- A. With pulmonary embolism.
- B. Tachy-apsychia from coughing (whooping cough, chronic bronchitis and alcoholics).

VII.—Failure to fill the right auricle.
- A. Fainting after unaccustomed exertion.
- B. A factor in ordinary faints, especially standing.
- C. ? postural hypotension.

VIII.—With cyanosis (asphyxia).
- A. With congenital heart disease.
- B. With Cheyne-Stokes respiration.

TABLE I (*continued*)

IX.—Unclassified.
- A. Hypertensive crises.
- B. With labyrinthine vertigo (falling common, unconsciousness rare).
- C. Gowers' syndrome (vaso-vagal).
- D. Cerebral effect of carotid sinus pressure without change of rate or fall of blood pressure.
- E. Cerebral embolism.
- F. Hypoglycæmic attacks.

[The speaker quoted examples of some of these varieties, especially with Stokes-Adams attacks, with aortic stenosis, with sudden attacks of coughing, and the many varieties with cardiac infarction.]

REFERENCE

ROSSEN, R., KABAT, H., and ANDERSON, J. P. (1943) *Arch. Neurol. Psychiat.*, **50**, 510.

Dr. M. N. Pai: Nearly every case of faints, fits and "blackouts" which does not respond to immediate treatment is likely to be referred to a psychiatrist on the assumption that treatment along psychiatric lines is indicated. On account of the socio-economic and medico-legal implications the psychiatrist who handles such a case is assuming a much greater responsibility than the neurologist unless he first satisfies himself as to the accuracy of the diagnosis. A subsequent diagnosis of epilepsy (made by the psychiatrist) may shatter the patient's faith in doctors, make him more hypochondriacal and induce in him a state of secondary anxiety which may again obscure the initial symptoms.

In the case of a member of the Forces a mistaken diagnosis of epilepsy may bring him some immediate advantages in the form of a discharge from the Forces and perhaps a high-percentage pension for life. The disadvantages are that he may be unnecessarily condemned to an indefinite period of anti-convulsant drug therapy with its occasional risk of intellectual deterioration and may also be precluded from obtaining employment commensurate with his intelligence and experience. There is also the stigma attached to epilepsy and considerable distress may be caused to his relatives.

On the other hand a hasty diagnosis of hysteria merely because the features of a fit do not conform to those of typical epilepsy may be tantamount to accusing the patient of evading his military obligations and civilian responsibilities. Sensible persons and their intelligent relatives resent such a diagnosis. If any Service person is invalided out on account of hysteria he may not only be denied a pension but may also have considerable difficulty in finding suitable employment. The rehabilitation of such persons is taxing the resources of psychiatrists, social workers and officers of the Ministry of Labour.

It is undesirable to diagnose epilepsy on the E.E.G. alone. For instance, in 1940–42 it was thought that an abnormal hyperpnœa response was evidence of epilepsy, quite a large number of patients suffering from hysterical fits and fainting attacks were diagnosed as epileptic and many were discharged from the Services on the basis of erroneous views about the E.E.G. The E.E.G. technique has improved considerably during the war and since about 1944 it has been recognized that an abnormal hyperpnœa response unrelated to the level of blood sugar has no significance.

Knowledge of this subject is now crystallizing and a positive E.E.G. may certainly help in clinching the diagnosis in any doubtful case. When a series of Service and civilian cases complaining of faints or fits were investigated by the E.E.G., it was found that a family history of fits, faints, psychoses and mental defect was commoner in those suffering from epilepsy than in those suffering from hysteria. The E.E.G. was also found useful in spotting epileptic equivalents. In one epileptic patient when the fits ceased there were for four years recurrent attacks of headaches and when these ceased there was periodic epistaxis for which no obvious cause could be found. The E.E.G. showed spikes, and administration of luminal controlled the epistaxis. In another patient with fainting attacks there was paroxysmal tachycardia and the E.E.G. showed paroxysmal outbursts diagnostic of epilepsy. In yet another patient when the fits were controlled there was sudden onset of compulsive-obsessional symptoms, e.g. washing hands; the E.E.G. showed the spike and wave pattern.

A diagnosis of epilepsy should be made with great caution and only after taking into consideration a reliable family history, details concerning previous health obtained from independent sources, careful observation of the fits and the E.E.G. During an attack the one positive physical sign which if present is pathognomonic of loss of consciousness and therefore in favour of a diagnosis of epilepsy is an extensor plantar reflex. Too much dependence on the E.E.G. alone may result in neglect of clinical observation and investiga-

tion with sometimes disastrous consequences. One of the patients sent to me as a case of hysterical faints had well-marked aortic regurgitation, another had advanced lymphosarcoma of the mediastinum and yet another patient was suffering from acute post-vaccinal encephalomyelitis.

Dr. W. Ritchie Russell emphasized that all brains can be made to discharge an epileptic fit, but in the so-called epileptic the threshold is low. In diagnosis there is no substitute for a careful record of what happened during a fit. Fit forms which can easily be posted to someone who saw the attack are of great value and should be widely used in out-patient practice. Elderly arteriosclerotic subjects sometimes have a fit while sleeping in a chair after a meal; this is preceded by pallor of the face and is probably due to cerebral anæmia. Those who suffer from postural syncope should be made to realize that they can prevent fainting if they at once stoop say to adjust their shoe-lace, of if they voluntarily contract strongly the abdominal and thigh muscles.

Dr. Sheila Sherlock: During fainting there is not only release of posterior pituitary extract but other evidence suggests that adrenaline is also liberated. Moreover, there is a re-distribution of blood in the body; the flow through the limb muscles increasing and that through the splanchnic area diminishing. All these events are apparently the effects of fainting. What is uncertain is the exact stimulus that sets this train of events in motion. For instance, is the abnormal rhythm which Dr. Denis Williams observed in the electroencephalogram a result of the faint rather than related to its causation?

Dr. Denis Williams, in reply to Dr. Sherlock: as the abnormal rhythms are present when the patient is in a normal state of consciousness they are presumably related to the basic cause of the instability, and are not an effect of the fainting.

Dr. Charles Baker: A not uncommon, but often unrecognized, cause of loss of consciousness is coughing. This was first described by Charcot in 1876 as laryngeal vertigo, with analogy to labyrinthine vertigo; and these cases have also been classified as laryngeal epilepsy. When my interest was aroused in this syndrome I had no difficulty in finding 9 cases; all were males, all were overweight, and chronic bronchitis and emphysema were common features. These features in the clinical picture were confirmed by a review of a fairly extensive literature, predominantly French (Baker, 1949). The mechanism both of faintness and loss of consciousness from coughing would appear to be a diminished flow of blood to the heart due to increased intrathoracic pressure when the glottis is closed; recent reports of cardiac catheterization during straining and coughing and positive pressure breathing tend to confirm this explanation. This is different from the carotid sinus syndrome. Emphysema would tend to augment the raised intrathoracic pressure owing to the absence of the elastic recoil of the lung; obesity would contribute to the diminished return of blood to the heart from the inferior vena cava by the loss of abdominal musculature; the occurrence in males is explained by the simple fact that men cough harder than women. The prognosis is good and the attacks are not dangerous though one man was reported as killing a pedestrian when he lost consciousness from coughing while driving his car; he was saved from a charge of manslaughter on the medical evidence.

JOINT MEETING WITH THE SOCIETY FOR THE STUDY OF ADDICTION

Biochemical Methods in the Treatment of Alcoholism, with Special Reference to Antabuse[1]

By ERIK JACOBSEN, M.D. (Copenhagen)

LIKE fire, alcohol is a good servant but a bad master. Why is it that for most of us alcohol is and remains a servant and why that for some of us alcohol becomes the master? There are two schools of thought: some explain this in terms of the victim's biochemical make-up, others explain it in terms of his psychological make-up. The truth is generally to be found mid-way between the two extremes, and even die-hard physiologists admit

FIG. 1.—Factors leading to alcoholism and consequences of alcoholism.

that to be effective, biochemical treatment of alcoholism must be accompanied and followed up by common-sense psychotherapy. In this paper, therefore, despite its biochemical title, due consideration will be given to the psychotherapeutic side of the problem.

We shall begin by trying to find something in common in the different points of view put forward about the ætiology of alcoholic addiction. Fig. 1 shows on the left the factors leading to alcoholism, and on the right its consequences. Free access to alcohol is of course essential for the development of alcoholism, but only in conjunction with other factors present either in the patient's milieu (here called external factors), or in the patient himself

[1]From the Biological Laboratories of Medicinalco Ltd., Copenhagen S.

(the internal factors). Among the external factors, bad social conditions, such as seen in slums, and poor farming districts, family dissension, financial and other personal worries may directly or indirectly lead to alcoholism. Drinking among one's friends, colleagues or mates are other external factors to be considered.

In addition to this, the patient himself must in some way or other be disposed to alcohol addiction, but it is difficult to reach agreement about which factor or factors are essential. Some workers lay stress on anxiety or Freudian complexes, others on a psychopathic constitution: a lack of ability to adapt oneself to life. In the psychiatric literature we find many attempts to describe what constitutional factors alcoholics have in common, but these efforts have not led to clear results. Some people acquire a compulsion to continue drinking when they have taken a certain amount of alcohol. Such persons run a great risk of becoming alcoholics, especially when the necessary amount of alcohol (here called the "critical dose") is relatively small. Other workers are inclined to attribute alcoholism to biochemical or metabolic disturbances (for instance in the carbohydrate or the citric acid metabolism), but their views are not accepted by all.

Probably there is no single cause of alcoholism, but a series of causes varying from patient to patient. In some cases the external factors predominate while internal constitutional factors play no more than a minor role, in other cases the predominance of internal factors (whatever they may be) cannot be denied, but even here the combination of factors may vary from case to case.

Once developed, alcoholism leads to effects which come under these three groups: social decline, medical effects, and psychological and metabolic effects. Some of these, of course, aggravate the existing alcoholism. The social decline reinforces the already existing external factors which originally led to alcoholism. The psychological effects may also augment the trend towards alcoholism, for instance, neuroses may develop which are drowned in more alcohol. Needless to say, the resulting moral deterioration does not improve the situation, and lastly it is well known that the alcoholized organism craves for more alcohol. Owing to such vicious circles, once started, the addiction develops steadily. Sometimes the factors which originally lead to alcoholism become of minor importance in the maintenance of addiction compared with the vicious circle itself.

Prophylactic and therapeutic measures can be taken against alcoholism at the three main points marked by the letters A, B, and C in Fig. 1. Table I shows what forms of treatment may be directed against these.

TABLE I.—EXAMPLES OF THERAPEUTIC MEASURES WHICH CAN BE TAKEN IN THE TREATMENT OF ALCOHOLISM

A. *Adjusting "internal factors"*
- Explanation of the character of the addiction.
- Psychotherapy of neuroses.
- Group therapy such as "Alcoholics Anonymous".
- Religious influence through Church, Salvation Army, &c.
- Moral influence through Temperance Societies.
- Moral influence by threat of legal procedures.
- Medical treatment of metabolic disturbances (if present).
- Treatment of compulsory craving (if present) by insulin-glucose or alcohol intravenously, &c.
- Treatment of anxiety with apomorphine. After Dent [20].

B. *Withdrawal of alcohol*
- Segregation in mental hospital.
- Aversion treatment with emetin.
- Hypnosis.
- Antabuse.

C. *Adjusting "external factors"*
- Regulating patient's family life and home conditions.
- Educating patient's relatives.
- Helping to improve patient's social position.
- Adjusting patient's economic conditions.
